Abstract

Inter-crystal scatter (ICS) in PET detectors causes multiple interactions within a detector block, and misidentification of the first interaction crystal can lead to incorrect LOR assignment and image degradation. Rejecting all ICS events avoids this error but reduces system sensitivity. This study proposes a stochastic conditional-probability-based ICS positioning method using ordering information from deposited energy and DOI. The method estimates first-interaction events by applying conditional probabilities defined over binned observables, where the conditioning variable is either the energy or DOI difference between two crystals involved in an ICS event. These probabilities were obtained statistically from GATE simulations of an 8×8 LYSO crystal array with 3.2 mm pitch. Point sources were placed at 5, 10, 20, and 25 cm, and two-crystal ICS events were selected for validation. The effects of bin count, binning strategy, and detector resolution were evaluated using 2, 4, and 8 bins with equiquantile and equal-width binning. Accuracy exceeded 85% using only 3% of the validation data, corresponding to approximately 20,000 ICS counts per detector block. DOI-based conditioning achieved slightly higher accuracy than energy-based method, suggesting that DOI ordering provides useful geometric information for first-crystal identification. However, the performance difference was small, indicating that either DOI or energy ordering can be used depending on detector readout capability. Accuracy was insensitive to bin count, binning strategy, and detector resolution. These results demonstrate that reliable ICS positioning can be achieved using predetermined conditional probabilities matched to detector characteristics, supporting practical recovery of ICS events without requiring high detector resolution or excessive readout complexity.

This work has received funding from the European Union's EURATOM research and innovation program (AIDER project, G.A. 101061037).

Abstract

Compton cameras are electronically collimated imaging devices that reconstruct the origin of gamma rays using Compton kinematics, making them particularly suited for targeted radionuclide therapy (TRT), where conventional gamma cameras struggle with high-energy and low-activity emitters. The European project AIDER is developing a high-performance scintillator-based Compton camera to improve imaging and enable dosimetry in TRT, including targeted alpha therapy. Accurate Monte Carlo modeling is essential in this context for detector design and image reconstruction optimization. We present the validation of Compton camera simulations using GATE version 10, a major evolution of the Geant4-based Monte Carlo toolkit for medical physics with a Python based user interface. To this end, data acquired with MACACO1, a two-layer Compton camera prototype based on monolithic $LaBr_3$ scintillation crystals, developed at IFIC-Valencia, was employed. A Monte Carlo model of this system was previously validated using a dedicated Compton camera module in an older version of GATE based on legacy static macro-based files. In this work, the model was developed using GATE 10. The detector response was modeled by a digitizer chain that includes the measured energy and spatial resolution of the prototype. Time coincidences were obtained offline using a time coincidence window of 50 ns.

Simulated and experimental coincidence energy spectra showed good agreement despite small discrepancies at low energies. The angular resolution measure at 1275~keV was in good agreement between both simulated and experimental data with a relative difference of 0.7%. The validated framework for Compton camera simulations with the new GATE 10 modular version, provides a flexible platform for detector design and image reconstruction optimization.

Abstract

Whole gamma imaging (WGI) is a hybrid nuclear medicine technique under development at QST that integrates PET and Compton imaging by placing a scatterer detector ring inside a PET detector ring. This configuration is expected to enable simultaneous PET and SPECT tracer imaging and to allow high-sensitivity PET acquisition using radionuclides such as ^{89}Zr, which emit both positrons and prompt gamma rays. In this study, we investigated the feasibility of extending a previously optimized brain-dedicated WGI design to a whole-body configuration by scaling the scatterer-detector ring diameter. Our proposed system expands the scatterer detector ring diameter in the whole-body mode, and fills the missing data due to the detector gaps by a mechanical rotation. Monte Carlo simulations using Geant4 were performed to evaluate the detection performance of the proposed system for ^{89}Zr imaging in the whole-body mode, with particular emphasis on the effects of inter-detector gaps introduced by geometric scaling and the necessity of mechanical rotation in the scatterer-detector system. Point-source simulations were conducted to assess Compton sensitivity and angular resolution measure (ARM), and sparse detector configurations were reproduced by masking half of the scatterer detectors. The results showed that Compton sensitivity was approximately doubled when all scatterer modules were installed, indicating that sensitivity is primarily determined by the number of available detectors rather than the presence of gaps. In contrast, ARM exhibited minimal variation across configurations, suggesting that mechanical rotation has little influence on angular-resolution performance. These findings provide essential design guidelines for whole-body WGI systems and will be further validated through imaging simulations to quantify the impact of detector gaps and rotation on reconstructed image quality.

Translating CLS Detector Technology from Brain to Whole-Body PET Imaging: A Simulation Study (#3161)

Mizuki Furuta[1,2], Hideaki Tashima[1], Go Akamatsu[1], Taiga Yamaya[1]

[1] National Institutes for Quantum Science and Technology (QST), Department of Advanced Nuclear Medicine Sciences, Chiba, Japan; [2] Chiba University, Faculty of Engineering, Chiba, Japan

Abstract

We have achieved 1 mm rod separation performance in a brain-dedicated PET system, CLS-7, which employs our original crosshair light-sharing (CLS) detector with both time-of-flight (TOF) and depth-of-interaction (DOI) capabilities. From that work, our next question to explore is how CLS technology can improve whole-body PET imaging. PET is widely used in cancer diagnosis, and improving spatial resolution with low image noise is important for detecting small lesions at earlier stages. In this study using Monte Carlo simulation, we investigated the imaging performance of a whole-body PET system using CLS detectors. A whole-body CLS-PET system was modeled using the Geant4 with a ring diameter of 750 mm and an axial field-of-view of 228 mm. The detector was modeled as a 14 × 14 LGSO crystal array with 1.45 × 1.45 × 15 mm³ crystals divided into three depth segments for DOI modeling. The system had 92 detector blocks per ring and seven rings. Spatial resolution and image quality were evaluated by simulating point-source and image quality phantom measurements based on the NEMA NU 2 standard and compared to cases with and without DOI and TOF information. As a result, we found the use of DOI information improved spatial resolution by 40% compared with the no-DOI information condition, while TOF information substantially reduced image noise in the image-quality evaluation. These results suggest that whole-body PET using CLS detectors can suppress peripheral spatial-resolution degradation and improve contrast recovery for small lesions.

Abstract

Reducing radiation dose in positron emission tomography / computed tomography (PET/CT) is possible, but ultra-low-dose (ULD)-CT increases image noise which may affect quantitative reliability and accuracy due to attenuation correction. Photon-counting CT (PCCT) offers improved noise characteristics compared with conventional energy-integrating detector CT (EID-CT), particularly at low dose levels. This study compares PCCT and EID-CT under low-dose (LD) and ULD-CT conditions using a cadaver, an anthropomorphic phantom (PBU-60), and a tissue characterization phantom (Gammex 467). Quantitative evaluation is performed using CT values in HU and corresponding linear attenuation coefficients (μ). Results show that ULD increases noise in both systems, with stronger degradation and reconstruction dependency in EID-CT. Compared with EID-CT, PCCT shows less changes in mean HU values between LD and ULD acquisitions, particularly in dense materials, although noise remains present. After HU-to-μ conversion, variability is substantially reduced for both systems, though not uniformly across all conditions. These findings indicate that attenuation coefficients are less sensitive to dose reduction than CT values and suggest that PCCT may provide more robust quantitative performance than EID-CT under ULD conditions. However, given non-matched acquisition and reconstruction settings results should be interpreted with caution, and require validation in further standardized and PET-based studies.

Abstract

Automated parcellation of the brain into correct regions using dual-modal PET and MRI is essential for quantitative neuroimaging. Existing high-performing fusion networks often rely on large model sizes, which limits their deployment in resource-constrained settings. This paper presents the DualModal Gated Residual Network (DMGR-Net), a lightweight architecture that integrates Bidirectional Cross-Modal Feature Gating (Bi-CMFG) and Residual Soft Deep Supervision (RSDS). Bi-CMFG performs spatial attention across modality-specific encoder branches to preserve fine structural details, while RSDS applies a boundary-weighted loss at multiple decoder scales to sharpen parcellation boundaries by explicitly penalizing errors along anatomical interfaces. Built upon a depthwise-separable 3D U-Net with only 0.121M parameters, DMGR-Net contains 0.206M parameters and 5.30 GFLOPs, yet achieves the lowest HD95 and ASSD among compared methods, surpassing substantially larger models on surface-distance metrics. Ablation studies confirm the complementary roles of each module, and qualitative comparisons illustrate progressively refined boundaries across configurations, demonstrating that a lightweight design can deliver precise surface delineation.

Abstract

Combined PET/MRI is a powerful tool for studying neurological diseases, but resolving cortical structures requires a spatial resolution of about one millimeter. Dedicated brain inserts can achieve this by bringing high-resolution detectors close to the head, provided that the detector electronics meet stringent constraints on integration, thinness, width, length, and MRI compatibility.

The S-PET project develops such a scalable PET detector platform for neuro PET/MRI. The detector module concept is built around a single mounting and cooling structure that spans the full module length and carries sensor tiles, mainboard, and power supply.

The Visor HD sensor tile (49 × 49 mm²) combines a 12 × 12 Broadcom 4 mm NUV-MT SiPMs with a PETsys TOFPET2 ASIC. A dedicated compression scheme maps the 144 SiPM outputs to its maximum 64 ASIC channels: 36 SiPMs are read out directly, while the remaining channels each combine four spatially separated SiPMs that can be disambiguated through their direct neighbors.

The SuperVisor mainboard (134 × 49 mm²) hosts six sensor-tile connectors, an AMD/Xilinx Kintex-7 FPGA, individual voltage and current regulation per tile, and fiber-optic transceivers on a second PCB layer to keep the board short. A separate, exchangeable power-supply board feeds the module.

Thin flex-PCB tile cables, produced in precise lengths up to 454 mm, connect the sensor tiles to the mainboard on the opposite side of the cooling structure.

A first measurement with a BrainPET 7T crystal array (three DOI layers of LSO at 2 mm pitch), scanned across a fan-beam-collimated ^{22}Na source, yields a mean absolute error below 1.4 mm in both planar directions, confirming that the Visor HD compression scheme works as intended. SuperVisor PCBs are in production and expected in time for the conference.

Abstract

Simultaneous positron emission tomography/magnetic resonance imaging (PET/MRI) can combine PET functional information with MRI soft-tissue contrast in a single imaging session, offering potential benefits for neurological applications such as neurodegenerative disease assessment and brain tumor localization. However, fully integrated PET/MRI systems remain limited, motivating the development of compact PET inserts that can operate inside or around existing MRI scanners. In this work, radiofrequency shielding was developed and evaluated as an enabling step toward an MRI-compatible Radialis brain PET insert using digital detector electronics. Shielding was implemented for the digital front-end modules, data-acquisition electronics, high-speed data-transmission cable, and auxiliary power cable of a Radialis PET detector array. Each detector module consisted of a 24 × 24 cerium-doped lutetium yttrium orthosilicate scintillator array coupled through a borosilicate light guide to an 8 × 8 silicon photomultiplier array. The shielded detector configuration was evaluated during simultaneous acquisition on a 3.0 T MRI system using a ^{22}Na point source in a water phantom positioned within the MRI brain-coil geometry. The redesigned shielding enabled stable PET data acquisition, coincidence processing, and point-source image reconstruction during MRI operation. PET energy resolution was maintained at approximately 22.5–22.6% during simultaneous acquisition, although reconstructed image signal-to-noise ratio decreased from 76.64 outside the MRI environment to 37.83 during PET/MRI acquisition, likely reflecting residual MRI-related effects, head-coil attenuation, and source-positioning differences. These results demonstrate that targeted shielding of Radialis digital PET electronics enables reliable simultaneous PET/MRI operation and supports further development of a high-sensitivity brain PET/MRI insert.

Design and Performance Evaluation of a Full-Ring SPECT System Based on the Continuous LaBr3(Ce) (#1199)

Kui Wang[1], Tiantian Dai[2], Qingyang Wei[1]

[1] University of Science and Technology Beijing, Beijing Engineering Research Center of Industrial Spectrum Imaging and School of Automation and Electrical Engineering, Beijing, China; [2] China–Japan Friendship Hospital, Department of Radiation Oncology, Beijing, China

Abstract

Small-animal single-photon emission computed tomography (SPECT) serves as a cornerstone of functional nuclear imaging, with extensive applications in preclinical research, drug discovery, and life sciences. Building upon our previously developed full-ring cascade gamma coincidence imaging system with continuous LaBr3 crystals, this work redesigns a multi-pinhole collimator to enable full-ring SPECT imaging for ^{99m}Tc. To optimize computational efficiency, the system transfer matrix is implemented using a sparse storage strategy. Furthermore, GPU acceleration is employed for key processes, including system matrix calculation, forward and backward projections, and image updates, significantly enhancing the performance of the iterative reconstruction algorithm. Experimental results demonstrate that the storage requirement for the system transfer matrix is reduced from 10.06 GB to 77.7 MB. Concurrently, the computational efficiency is significantly enhanced, achieving a single iteration time of 0.94 ms in binning mode. Moreover, the full-ring SPECT system achieves a 1.0×10^{-3} detection efficiency and successfully resolves 1.2 mm diameter hot rods. In conclusion, the proposed full-ring SPECT system achieves a high-performance balance between detection sensitivity and spatial resolution.

Abstract
At the Biomedical Imaging Laboratory of the Institute of Physics, UNAM, a dual-panel positron emission mammography (PEM) prototype is under development. This work evaluated its spatial resolution through the line spread function, and image quality via recovery coefficients. A custom variable-geometry phantom was developed using 3D-printed supports for four ^{18}F line sources with a 0.69 mm internal diameter. Data acquisitions were performed at 11 in-plane positions and at different cross-planes heights to map the 17.4 cm × 17.4 cm × 6.0 cm effective field-of-view. Experimental setup included a panel separation distance of 6.0 cm, 8 ns coincidence window and a 360 – 757 keV energy window. The interaction position of each event is estimated using a raise-to-a-power center-of-gravity algorithm. Images are reconstructed using a list-mode ordered subsets expectation-maximization algorithm (3 iterations, 4 subsets) using a 1 mm isotropic voxel. Image quality was evaluated with a NEMA-like phantom containing 4 spherical lesions (diameters of 4, 6, 8 and 10 mm) filled with ^{18}F, placed at different field-of-view positions and phantom orientation. The effect of restricting oblique lines of response was also studied. In addition, the sensitivity was analyzed using a point-like ^{22}Na source in different field-of-view positions. The best spatial resolution was 2.1 ± 0.2 mm at the center of the PEM field-of-view and decreasing to 4.5 ± 0.3 mm at the PEM edges. FWHM values closest to the real sphere diameters were obtained at the detector center. Limiting oblique lines-of-response to reduce depth-of-interaction effects resulted in lower spatial resolution. Overall, the prototype showed good performance, with adequate image quality regardless of spherical-lesion position or orientation.

Abstract
Monolithic scintillators are a promising alternative to standard pixelated crystals in positron emission tomography, as they can be more cost-effective, reduce dead space, and capture an unobstructed light distribution, which can be used for depth of interaction estimation. We focus on the improvements seen by using an array of integrated

corner reflectors (ICR) machined directly into the entrance face of the monolith, which we previously showed via simulation to improve light collection and narrow the light distribution. In this study, we built a physical prototype of the device using a CNC machining process. We compared this prototype with other monolithic block designs. We show that the ICR monolith with the CNN positioning algorithm has potential for high-resolution imaging with ~1 mm resolution at 12 mm thickness. Using GATE simulations, we constructed a full scanner with the performance of the monolithic blocks and tested the capabilities compared to existing systems. We show the improved spatial resolution and feasibility for a non-cylindrical design for axillary lymph node scanning.

Abstract
Pixelated crystal arrays are the standard in commercial PET scanners. However, these detectors usually lack DOI information, essential to achieve a homogenous spatial resolution along the entire FOV. Yet, studies have been already performed with pixelated detectors with DOI capabilities but at the cost of using extra hardware material and/or crystal assembling. Inspired by semi-monolithic crystal geometries, pseudo-slabs were proposed as an alternative. This geometry consists of an *N*×*N* pixel array optically isolated only in one direction, allowing light crosstalk in the orthogonal one. The *N* pixels sharing light in this direction form a pseudo-slab. The light sharing within a pseudo-slab is enough to enable DOI retrieval, while the physical separation between pixels confines the light more than in a pure slab geometry, yielding better time resolution.

In this work we evaluated the DOI resolution of a BGO block formed by 8×8 pixels, each measuring around 3×3×15 mm^3. Two different readout configurations were employed and compared. First, all the 64 channels corresponding to the TOFPET2 ASIC channels were digitized. Then, a multiplexing circuit was utilized, reducing the signals to 8+8 by summing rows and columns. The DOI was obtained using neural networks trained on experimental data.The results show a good DOI resolution for both readout configurations, achieving 3.8 ± 1.3 mm with the multiplexing circuit. These results show that pseudo-slabs are suitable for clinical PET scanners with DOI capabilities.

Abstract

The spatial resolution of PET imaging is fundamentally limited by the positron range, whose extent depends on both the emission energy of the radionuclide and the electron density of the surrounding medium. In integrated PET/MRI systems, the static magnetic field exerts a Lorentz force on the positrons, confining their trajectories in the transverse plane to the main magnetic field, potentially improving image resolution. Two complementary experiments were performed using a dedicated monolithic-crystal based PET insert operated at 0T and inside a 9.4T MRI: capillary line sources embedded in three tissue-equivalent phantoms of increasing density (EPF, PLA, and Rigid10k resin), and a microDerenzo phantom. Both tests were carried out with three positron emitters (^{18}F, ^{89}Zr, and ^{68}Ga) eventually use in pre-clinical imaging. The results demonstrate that the magnetic field significantly enhances transverse spatial resolution for high-energy positron emitters in medium- and high-density materials, with FWTM reductions of ~60% for ^{68}Ga and ~18% for ^{89}Zr, while the axial direction remains largely unaffected. Rod resolvability improved at 9.4T from 1.5 mm to ~1.0 mm and from 1.2 mm to 0.9 mm for ^{68}Ga and ^{89}Zr, respectively. . These findings highlight the relevance of both positron energy and tissue-equivalent density in determining the magnitude of magnetic-field-induced resolution improvements in preclinical PET/MRI.

Abstract

The aim of this study was to optimize detector parameters of crosshair light-sharing (CLS) detectors to achieve a better resolution-sensitivity balance in the CLS-7, a brain-dedicated PET prototype we developed in 2025. In particular, we focused on position lookup tables (LUTs), which are generated from flood histograms calculated using Anger logic. In the 2025 model, restricted position LUTs fitted to crystal clusters were used to reduce inter-crystal scattering (ICS), thereby improving spatial and time-of-flight (TOF) resolution at the cost of decreased system sensitivity. In this study, we employed expanded position LUTs and compared the performance of restricted and expanded LUTs in the CLS-7. The detectors consisted of 15-mm-long fast-LGSO scintillators arranged with a crystal pitch of 1.6 mm. Sensitivity, noise-equivalent count rate (NECR), and TOF resolution at the peak NECR were evaluated for both settings. In addition, image quality was evaluated using a rod phantom, an IQ phantom, and a Hoffman phantom. Compared with the restricted LUTs, the expanded LUTs significantly improved sensitivity and the peak NECR by factors of 1.7 and 1.9, respectively. The loss in TOF resolution was only 12%, and no significant difference was observed in the rod phantom results. In both the IQ phantom and the Hoffman phantom, images obtained using the expanded LUTs had lower noise levels than those obtained using the restricted LUTs. These results demonstrate that expanded position LUTs can improve overall image quality despite some degradation in TOF resolution in the CLS-7 system.

Abstract

This study presents a performance evaluation of N-PET, a high-resolution TOF-DOI PET system designed for human brain imaging. The system has a compact ring geometry comprising 18 detector modules, with a ring diameter of 302 mm, a transaxial FOV of 210 mm, and an axial FOV of 52 mm. Each module employs dual-layer, multi-resolution LYSO detectors that enable both high spatial resolution and DOI measurement.System performance was first evaluated through count-rate measurements and phantom studies. Using a monkey-sized phantom, the scanner achieved a peak NECR of 44.0 kcps at 66.8 MBq, with a scatter fraction of 36.0%. After component-based normalization, the images of an image quality phantom showed a uniform background and high contrast hot spheres. Hot rod phantom imaging further demonstrated the high resolution of the system. With the phantom placed at the center of the FOV, rods of 1.2 mm diameter were resolved. When the phantom was placed at a 5-cm radial offset, reconstructed images using four DOI bins yields improved rod separation compared to that with one or two DOI bins, highlighting the benefit of DOI information in reducing resolution degradation near the edge of the FOV. In the Hoffman brain phantom images, gray matter structures are clearly delineated, and the PET images correlated well with anatomical structures derived from the CT image.

The imaging performance of N-PET was further evaluated in animal studies. In small animal scans, a rat ^{18}F-FDG imaging visualized the rat heart, while ^{18}F-NaF imaging clearly depicted rib structures. In a rhesus macaque brain study, PET and fused PET/CT images revealed major brain anatomy, with elevated FDG uptake in the cerebral cortex and subcortical nuclei. These results demonstrate that N-PET can provide high-resolution PET images in phantoms, small animal, and non-human-primate studies, supporting its feasibility for human brain imaging studies.

Abstract

We have developed a high resolution small-animal in-beam PET scanner as part of the SIRMIO project for accurate image-guided proton irradiation at clinical facilities. The scanner consists of 56 three-layer depth-of-interaction (DOI) LYSO detectors with 1.0 mm-pitch scintillator pixels arranged in a compact spherical geometry with a with an entrance radius of 72 mm. Using different irradiation platform, we successfully demonstrated small-animal in-beam PET imaging. Since the number of positron emitters generated during irradiation is limited by the prescribed dose, intrinsic Lu background can contribute to background noise. In this study, we investigated the optimal energy window settings for different activity levels using Monte Carlo simulations based on coincidence count statistics in the SIRMIO PET scanner. The three-layer DOI detector structure enables independent energy window settings for each DOI layer. Since 511 keV gamma rays are more likely to interact near the shallow side of the detector, wider energy windows were selectively applied to shallow DOI layers, while narrower windows were used for deeper DOI layers to suppress Lu-176 background contributions. Geant4 simulations were performed for source activities ranging from 0.05 to 50 kBq. Net significance was evaluated for combinations of lower energy thresholds of 250 - 450 keV with a fixed upper threshold of 600 keV. For low-activity cases such as 0.05 kBq, the optimal lower energy thresholds were 400, 450, and 450 keV for the first, second, and third DOI layers, respectively. In contrast, wider energy windows became more advantageous at higher activity levels. These results indicate that layer-dependent energy window optimization is an effective method for improving low-count in-beam PET imaging performance.

NEMA NU-2 performance tests of a prototype PET scanner using novel detectors capable of measuring the gamma interaction point in 3D

(#2832)

August Blomgren[1], Benjamin Brunt[2], Marcus Palm[2], Christina Vallgren[2], Konstantinous Ziempekis[3], Marco Viscione[3], Axel Rominger[3], Kuangyu Shi[1]

[1] University of Bern, Department of Nuclear Medicine, Bern, Switzerland; [2] Terapet SA, Geneva, Switzerland; [3] Inselspital - University hospital of Bern, Bern, Switzerland

Abstract

Background: Depth-of-interaction (DOI) is one of the remaining challenges for high resolution PET. The resolution degradation stems from incorrect LOR endpoint estimation when photons impinge on the detector at oblique angles. This problem increases with distance from the symmetry axis and poses a challenge for LAFOV PET, where more LORs are acquired at oblique angles. Terapet SA manufactures radiation detectors capable of localising gamma ray interactions in 3D within the detector volume, potentially mitigating this effect. The aim of this project was to characterise the performance of a prototype PET scanner using Terapet's proprietary detectors, particularly the potential of DOI artefacts reduction.

Method: The NEMA NU-2 performance tests were conducted at the Department of Nuclear Medicine at Inselspital, Bern. Additionally, so far, two patient scans have been performed.

Results: The prototype achieved a FWHM of 2.56, 2.60 and 2.96 mm, averaged over all axes, at 10, 100 and 200 mm radial offset, respectively. The loss of resolution with increasing radial offset was lower in the prototype than in other clinical scanners, particularly along the radial axis.

The prototype had a low detection sensitivity of 0.99 cps/kBq. This is explained by the restrictive selection requirements on single- and coincidence events, optimised for high-quality data rather than high sensitivity.

The image-quality phantom and two patient images have been acquired. Results will be presented at the conference. The expectation is improved contrast recovery due to the improved spatial resolution, particularly for the smallest sphere.

Conclusion: The prototype demonstrated improved spatial resolution with the proprietary detectors. In particular, the spatial resolution is maintained with increasing radial offset. Future work will be aimed at improving the image reconstruction algorithms and correction methods. Construction of a LAFOV scanner using the same proprietary detectors is ongoing.

SurfaceCam: A Close-Proximity Multi-Pinhole CZT Brain SPECT system with Enhanced Geometric Sensitivity and Spatial Resolution (#3121)

Shubham Mandot[1], Scott D. Metzler[2], Ling-Jian Meng[1,3]

[1] University of Illinois at Urbana-Champaign, Department of Nuclear, Plasma and Radiological Engineering, Champaign, USA; [2] University of Pennsylvania at Philadelphia, Department of Radiology, Philadelphia, USA; [3] University of Illinois at Urbana-Champaign, Beckman Institute for Advance Science and Technology, Champaign, USA

We would like to thank NIH/NIBIB (BRAIN Initiative) for supporting this work under the grant UG3 EB034715.

Abstract

High-sensitivity, high-resolution brain-dedicated SPECT systems are critically important for advancing diagnosis and surgical planning in complex neurological disorders such as epilepsy, Parkinson's disease, and Alzheimer's disease. In this paper, we present *SurfaceCam*, a close-proximity multi-pinhole SPECT architecture with a radially adaptable rotating gantry, designed specifically for clinical brain imaging. The system comprises 15 detector-collimator panels distributed across three detector heads in a cylindrical arrangement, operating at a 1:8 minification geometry with a 28 cm bore. Each panel integrates 16 high-performance CZT sensors in a compact 2×8 configuration. The three detector heads translate radially to accommodate varying patient head sizes while maintaining close-proximity geometry, and the rotating gantry enables micro-rotation between acquisitions to facilitate angular super-sampling strategies. Pinholes are organized into groups of four with a twisted geometry, each subtending partial coverage of the 20 cm spherical FOV, while eliminating inter-pinhole projection multiplexing on the detector surface. Analytical comparison against a conventional 1:11 minification compound-eye reference design demonstrates approximately 1.4-fold higher geometric sensitivity and approximately 27% improvement in effective pinhole spatial resolution. The front-end electronics and data acquisition systems have been fully developed and validated, with Monte Carlo simulation studies and experimental phantom validation currently underway.

Abstract

α-emitting radiopharmaceutical therapies (αRPT) show great potential to treat solid and diffuse tumors. However, following α-decay, the recoil energy and chemistry of daughter isotopes separate them from the targeting vector, exposing healthy tissue to an elevated radioactive dose. These effects must be studied in small animal experiments before new αRPTs make it to clinical trials. However, since extremely low activities are used, current single-photon emission computed tomography is insufficient due to its low sensitivity, especially for the 440 keV gamma ray emitted by ^{213}Bi (a daughter of one of the most promising radionuclides for αRPT, ^{225}Ac). In previous work, we used a high-purity Ge Compton camera as a high-sensitivity solution for pre-clinical imaging of αRPT. We demonstrated quantitative Compton imaging of ^{213}Bi using total-variation maximum-*a posteriori* expectation-maximization and a post-reconstruction global activity calibration. In this work, we improve upon this by implementing non-region-of-interest (nROI) reconstruction and a Gaussian Process Prior (GPP). We image a mouse phantom at relevant activity concentrations and measurement times to demonstrate that nROI reconstruction mitigates artifacts by redistributing events outside of the field-of-view across the image. We also show that, by using a GPP that correlates the activity in proximate voxels, we improve activity concentration quantification in all the volumes of the mouse phantom with respect to ML-EM. We modify both methods from previous iterations for local activity and uncertainty quantification, which is not straightforward in conventional ML-EM, and compare uncertainties obtained with the Laplace Approximation and preconditioned Crank-Nicholson Markov-Chain Monte Carlo to explain discrepancies from the ground truth. Finally, we experimentally measure a spatial resolution of ~3mm FWHM with a mini-Derenzo phantom.

The author would like to express sincere appreciation to the supervisor and colleagues of the team for their support.

Abstract

Grating-based X-ray interferometry dark-field (DF) imaging provides exceptional sensitivity for detecting microstructures below the spatial resolution of standard detectors. Traditionally, this technique requires either large-scale synchrotron facilities or the integration of a source grating into a conventional X-ray tube setup. This study investigates a compact, simplified Talbot interferometer configuration utilizing a microfocus X-ray tube paired with a pixelated, energy-resolved photon-counting detector. In this setup, the microfocus source ensures the necessary spatial coherence, while the detector's energy-resolving capability enables the selection of specific energy bins—directly correlated to wavelength—to optimize reconstruction at the pixel level. Validation was conducted by imaging a metallic screw (0.5 mm pitch) using the phase-stepping method. Results demonstrate that while the sharp thread lines were heavily blurred in attenuation and phase-contrast modalities, they were clearly resolved in the dark-field images. Two optimization methods were evaluated for the full-energy dataset. Method 1, based on fitting effect correction through pixel filtering and interpolation, increased the Contrast-to-Noise Ratio (CNR). Method 2, based on the probability distribution approach, further improved the dark-field image quality compared to Method 1. This method resulted in a brighter signal along the threadline and significantly fewer rejected pixels, ensuring a more complete and better-defined representation of the object. These results demonstrate that high-resolution dark-field imaging is achievable through a compact laboratory setup combined with targeted data-processing optimizations.

Abstract

Virtual X-ray imaging experiments are a crucial research technique in the development of X-ray technology. In recent years, advanced imaging detectors, such as photon-counting detectors, have been developed and are increasingly being used in clinical applications. It further increases the importance of virtual X-ray imaging experiments. To improve the reproducibility of patients in virtual experiments, the development of digital phantoms having diseases is desired. The purpose of this study is to develop a procedure for creating digital phantoms that can reproduce diseases. Virtual monoenergetic images (VMIs) at 40 keV and 130 keV were generated using a clinical photon-counting CT (PC-CT) system, and effective atomic number (Z_{eff}) and effective physical density (ρ_{eff}) were calculated using a newly developed algorithm. Z_{eff} was calculated by using the correlation between the ratio of measured linear attenuation coefficient (μ) values and atomic number (Z). ρ_{eff} was calculated from the fitting coefficient obtained by fitting the reaction cross-section (σ) of each Z material to the measured μ values. Then, 10 patient data examined using PC-CT were analyzed, and digital phantoms were created. We investigated the reproducibility of Z_{eff} and ρ_{eff} values of the disease tissues. Our procedure could reproduce the disease tissues by continuous Z_{eff} and ρ_{eff} distribution. In conclusion, we developed a methodology for constructing digital phantoms of patients having diseases from VMIs acquired with PC-CT.

A novel computational scatter estimation method in CBCT with half ASG (#1343)

Jiongtao Zhu, Yuhang Tan, Zeqi Huang, Haodi Wu, **Yongshuai Ge**

Shenzhen Institutes of Advanced Technology, Chinese Academy of Sciences, Shenzhen, China

Abstract

CBCT image quality is strongly degraded by scattered radiation. Conventional anti-scatter grids (ASGs) are commonly used to mitigate this effect; however, they can only remove a portion of the scattered photons. In this study, we propose a novel computational scatter estimation method based on a half anti-scatter grid (h-ASG), which covers only half of the flat-panel detector. The full scatter distribution is estimated by combining two reconstructed CBCT images: one containing the full scatter component and the other containing a reduced scatter component. Experimental results using CatPhan and anthropomorphic head phantoms demonstrate that the proposed method effectively suppresses scatter-induced artifacts and significantly improves CBCT image quality.

Abstract

X-ray computed tomography (CT) is essential nondestructive internal imaging. Photon-counting computed tomography (PC-CT) acquires X-ray energy information to enable material identification and quantitative density evaluation. Combining PC-CT energy information with magnetic resonance imaging (MRI) data is expected to provide a novel diagnostic approach to visualize inflammation through tissue water fraction estimation. We developed a PC-CT system combining high-speed scintillators (YGAG:Ce) and silicon photomultipliers (SiPMs), specifically utilizing multi-pixel photon counters, MPPCs, which are optical semiconductor devices. This study evaluated healthy and fatty liver rat models (fed a high-fat diet for two or four weeks). Liver fat fractions, estimated from energy-dependent linear attenuation coefficients, showed good agreement with MRI and pathological results. Furthermore, we performed a detailed pathological evaluation focusing on inflammation induced changes in tissue water content. By integrating high reliability MRI fat fraction data with PC-CT data, we improved the estimation accuracy of water content and quantitatively visualized tissue ”water-richness” (edema). Increased water proportions in fatty liver groups suggested inflammation progression. These findings demonstrate that PC-CT is highly valuable for quantitative evaluation of liver disease within a multi-modality imaging approach.

Introducing “T-Index”—A Metric for Quantifying Data Range and Sampling Sufficiency (#2039)

Katsuyuki Taguchi, Jingyan Xu

Johns Hopkins University, Baltimore, USA

The work has been supported by NIH grants R01 NS126256, U01 EB037558, R01 EB036984, R21 EB034337, R21 EB033426, R21 EB037806.

Abstract

Many image reconstruction methods for x-ray computed tomography (CT) use optimization approaches with cost functions that consist of a data fidelity term and a prior term. Extensive efforts have been devoted to construct better priors, some using machine learning, for high resolution, low dose, and spectral imaging. There seems to be a belief that a good prior can overcome any problems in data acquisition, downplaying the data fidelity term. It would be desirable if we could quantify the sufficiency of the problem setting (or adequacy of the data acquisition) toward a set of desired imaging properties. We propose “Truth index” or “T-index” to quantify data range and data sampling issues in this work. When fully developed, the T-index will show, independent of specific image reconstruction methods used, how much the solution can be trusted or has a risk of hallucination.

Abstract

Photon-counting CT (PC-CT) is a powerful spectral imaging technique that identifies materials by counting individual X-ray photons. While direct-conversion systems are entering clinical practice, we are developing a cost-effective, large-area scintillator-based PC-CT system using YGAG:Ce coupled with silicon photomultipliers (SiPMs). PC-CT excels at identifying high-atomic-number elements like gold (Au) by utilizing its K-edge (80.7 keV). Gold nanoparticles (AuNPs) are promising for drug delivery, as their biodistribution can be controlled by particle size, enabling selective tumor accumulation via the enhanced permeability and retention (EPR) effect.

In this study, we evaluated the in vivo biodistribution of AuNPs in tumor-bearing mice using our SiPM-based PC-CT. Two sizes of AuNPs (1.9 nm and 15 nm) were intravenously administered, and their accumulation was quantitatively assessed using multi-energy CT concentration estimation. Results showed distinct size-dependent patterns: 1.9 nm AuNPs exhibited rapid renal clearance and bladder accumulation, while 15 nm AuNPs showed prolonged circulation and significant hepatic accumulation. Tumor accumulation was confirmed for both sizes, demonstrating the potential of our SiPM-based PC-CT for quantitative in vivo nanoparticle imaging.This presentation reports on the
experimental setup, the analysis methods, and the results obtained.

Abstract

Cone-beam computed tomography (CBCT) is a vital imaging modality rooted in nuclear science. It uses ionizing radiation and information processing to provide patients' internal anatomical details. When patients with metal implants undergo CT scans, projection data is contaminated. Consequently, reconstructions produce severe metal artifacts, compromising diagnostic accuracy. Thus, developing high-performance metal artifact reduction (MAR) methods for CBCT is essential for accurate clinical diagnosis. Some existing MAR methods ignore physical phenomena, like X-ray scattering, during imaging. Others use scatter correction as a preprocessing step; however, this non-end-to-end approach increases complexity. Here, we propose an end-to-end MAR method incorporating scatter correction and metal segmentation within the projection domain into a single network, followed by morphological post-processing and artifact suppression. Qualitative and quantitative analyses on simulated and real datasets demonstrate the superiority of this end-to-end method.

Abstract

In radiography imaging, dual-layer flat-panel detectors (DFDs) can be used for two purposes: acquiring high-quality x-ray images and performing material decomposition.

When using cone beam projection in DFD, the x-ray beam is scattered inside the object, increasing and distorting the intensity. In this paper, we experimentally observe x-ray scattering in acquiring images from DFD. The image acquired from the lower detector layer shows more scatter to prime ratios (SPRs) than the upper layer case due to the scattering inside the upper and intermediate layers. We perform parameter modeling for experimental SPR curves and simulations regarding the measurement of bone mineral density (BMD) estimates, including scattering intensity. We can observe that using the 2nd-order polynomial BMD function or fully connected neural network can successfully estimate BMD functions without scatter correction.

Abstract

The growing demand for accessible, high-resolution imaging in pre-clinical and materials research has driven interest in low-cost micro-computed tomography (micro-CT) platforms. In this work, a bench-top micro-CT system was designed, assembled, and experimentally characterized, built around a microfocus X-ray tube, a CMOS flat-panel detector, low-cost open-source electronics based on an STM32 microcontroller, and the open-source TIGRE toolbox for volumetric reconstruction. A step-and-shoot acquisition strategy --- in which the sample rotates incrementally, and the detector captures frames only during active X-ray exposure via a hot duration trigger mode --- was employed for synchronized image acquisition. Three reconstruction approaches were implemented and comparatively evaluated: filtered back projection (FBP), Feldkamp-Davis-Kress (FDK) algorithm as the primary volumetric reconstruction method, and iterative techniques for noise suppression. System performance was assessed through established phantom protocols evaluating image uniformity, noise, signal-to-noise ratio (SNR), contrast-to-noise ratio (CNR), and a QRM micro-CT Bar-pattern phantom for spatial resolution characterization. While a persistent precession artefact attributed to rotation stage mechanical instability was identified as the primary performance limitation, the system demonstrated tomographic imaging capability and sub-millimeter spatial resolution, establishing a promising foundation for the development of accessible and cost-effective micro-CT platforms for laboratory research.

Development of a Robot-Arm-Based Automated Transmission and Backscatter X-ray Image Acquisition System for AI Training Data Generation (#2733)

JeongHee Lee[1], Chang Hwy Lim[2], Jongwon Park[1], Youngchol Choi[1]

[1] Korea Research Institute of Ship & Ocean Engineering, Dejeon, South Korea; [2] XsCan Inc, Dejeon, South Korea

This work was conducted as a part of the research projects of “Development of automatic screening and hybrid detection system for hazardous material detecting in port container” financially (RS-2020-KS201398) supported by the Ministry of Oceans and Fisheries, Korea.

Abstract

A large-scale X-ray image dataset acquired under diverse specimen and imaging conditions is essential for developing robust AI-based container-structure inspection models. However, single-view transmission imaging often fails to resolve structural ambiguities in complex container environments, where X-ray attenuation and scattering characteristics vary significantly with specimen geometry, material composition, and overlap conditions. In this study, a robot-arm-based automated transmission and backscatter X-ray image acquisition system was developed to enhance the diversity, reproducibility, and traceability of AI training data. The system employs a 225 kV, 13 mA X-ray source to sequentially acquire vertical and horizontal transmission images and horizontal backscatter images. The transmission unit consists of 1,408 detection channels based on eleven 1×128-pixel line-detector modules, whereas the backscatter unit incorporates four 600×500 mm plastic scintillation detectors. By precisely controlling specimen orientation using a robot arm, the system stores acquired images together with preprocessing results, quality-assessment data, and imaging-condition metadata for subsequent AI model training, validation, and evaluation.

Abstract

We quantify the impact of scatter on the performance of bone suppression in virtual non-calcium chest radiographs (VNCa-CXR) generated with (i) a multi-layer flat-panel detector (ML-FPD, three 200-um thick CsI layers) and (ii) with a kV-switching protocol (60/140 kVp). We show that in the setting of log-subtraction, the decomposition weight (DW) can be adjusted for scatter-to-primary ratio (SPR) such that the scatter-induced bias in VNCa is locally corrected (scatter-compensating weight, DW-scat). However, DW-scat is spatially varying. If a constant DW is used in log-subtraction, the magnitude of bone residual in VNCa radiographs will depend on the degree of spatial inhomogeneity in DW-scat. We investigate this effect is simulation studies in anthropomorphic chest phantoms (20 – 24 cm thickness) with and without an anti-scatter grid (ASG). Without a scatter-compensating DW, scatter-induced bone residual increased by >100% is most configurations except for ML-FPD with a grid. Applying DW-scat averaged over central lung region reduced the residual by up to 50% for ML-FPD without an ASG and by ~40% for kV-switching with an ASG. Overall, our results reveal that DE VNCa imaging is relatively robust to scatter in scenarios with a grid, where kV-switching appears to benefit from spatially-averaged scatter-compensating DW more than ML-FPD, likely due to differences in scatter content of the two energy channels. Without a grid, both configurations may require a spatially-dependent scatter compensation for optimal bone suppression.

Time-of-Flight X-ray Imaging with Scatter Rejection and Subtraction

(#3042)

Abstract

X-ray time of flight information can be used in computed tomography to characterize photon interactions and discriminate scattered from unscattered events. Specifically, photons undergoing Compton and Rayleigh scattering are subject to trajectory deviations that increase their path length relative to primary photons. Therefore, with adequate temporal resolution, scattered photons are detected with larger time delay with respect to primary photons, providing a physically grounded mechanism to reject scatter. Recent technological developments in ultra-fast X-ray sources (e.g: 50ps) and high-temporal-resolution photon-counting detectors may allow for this imaging modality.

In this work, Monte Carlo (MC) simulations of a water cylinder were performed assuming Gaussian source pulse shape and detector timing jitter, with combined full-width-half-maximum as low as 50ps. A threshold-based scatter rejection method was applied, sweeping multiple thresholds to find the optimal balance between scatter rejection efficiency (η) and primary retention (ε). Filtered-backprojection reconstructions were performed and evaluated in terms of root mean square error and bias. Rejection performances were compared with an ideal, MC-based scatter subtraction technique, that leverages template fitting to estimate the average scatter contribution from time-delay histograms. A combined rejection-subtraction approach was also evaluated.For rejection only, the optimal reconstruction accuracy is obtained with a threshold T'=30 ps, corresponding to η=59% and ε=80%. Residual scatter leads to bias in the reconstructed attenuation, preventing the method from achieving the same reconstruction accuracy as the ideal subtraction. However, rejection yields lower noise levels compared to subtraction. Combining rejection and subtraction may provide a better compromise between bias and noise.

Iodine Sensitivity in Photon Counting CT Using Conventional and Diffusion-Based Material Decomposition Algorithms (#3123)

Suyu Liao[1], Grace J. Gang[1]

[1] University of Pennsylvania, Radiology, Philadelphia, USA; [2] University of Pennsylvania, Radiology, Philadelphia, USA; [3] University of Pennsylvania, Radiology, Philadelphia, USA

This work is supported, in part, by ARPA-H grant AY1AX000089.

Abstract

Spectral CT enables material-specific imaging but suffers from noise amplification in low-concentration iodine decomposition. This work investigates advanced material decomposition algorithms for improving iodine detectability in a simulated four-channel photon-counting CT system. Diffusion Posterior Sampling (DPS) with hybrid priors was compared with conventional image-domain and projection-domain decomposition methods. Results demonstrate improved noise suppression and low-concentration vessel detectability while highlighting the noise-bias tradeoff in diffusion-based material decomposition.

Abstract

Low-dose computed tomography (LDCT) is essential for mitigating radiation risks to patients, and its effectiveness is significantly enhanced by automatic tube current modulation (TCM) that optimizes photon allocation across different projection angles to maintain image quality at reduced doses. However, most traditional methods offer

fixed modulation strategies based on typical human phantoms, thereby ignoring individual anatomical variations and failing to achieve personalized dose allocation. This paper proposes a personalized TCM method driven by an end-to-end neural network (TCMnet). Specifically, we construct a differentiable optimization chain that integrates the modulation strategy, forward projection, and image reconstruction into a unified framework, allowing the system to learn optimal, patient-specific current profiles by directly minimizing reconstruction errors under specific dose constraints. Experimental results demonstrate that, under identical photon count (radiation dose) constraints, the proposed method yields significantly higher reconstruction quality compared to conventional approaches. By analyzing the performance of these optimized profiles across varying dose levels, this study reveals an important physical phenomenon: under extreme low-photon-count conditions where photon resources are severely limited, the optimal modulation strategy shifts from seeking a globally balanced noise distribution to concentrating photons on fewer key projection angles in high-attenuation regions. This finding not only validates the optimization capabilities of the end-to-end framework under complex constraints but also provides new insights and design concepts for TCM mechanisms for ultra-low-dose CT.

A Fully Quantitative Reconstruction Framework Tailored for Depth-of-Interaction PET Systems (#1140)

Yihao Chen, Ziquan Yuan, Yue Chen, Chenxi Li, Kexin Wang, Yucun Hou, Jianyong Jiang

Beijing Normal University, School of Physics and Astronomy, Beijing, China

This work was supported in part by the National Natural Science Foundation of China (No. 12475336), the Fundamental Research Funds for the Central Universities (No. 310400209521) and Beijing Natural Science Foundation (QY25290).

Abstract
Depth-of-interaction (DOI) encoding in positron emission tomography (PET) systems effectively mitigates parallax errors and improves spatial resolution, however, it introduces substantial complexities for accurate and efficient image reconstruction. Specifically, the dramatic increase in valid lines-of-response (LORs) and the inherent limitations of conventional correction methods—such as component-based normalization (CBN) and single scatter simulation (SSS)—often compromise quantitative accuracy in DOI enabled systems. To address these challenges,

we propose a fully GPU-accelerated reconstruction framework specifically designed for DOI-PET with complete correction techniques. The proposed framework extends standard CBN and SSS methods through sub-layer-based geometric modeling, enabling layer-specific normalization and scatter correction. A maximum-likelihood-based strategy is introduced to estimate DOI-dependent scatter scaling factors, incorporating inter-layer attenuation effects and axial response variations. The framework was evaluated using Monte Carlo simulations of the NeuroEXPLORER scanner. Our results demonstrate that the reconstructed uniform cylinder phantom exhibits high spatial homogeneity. Furthermore, the spatial resolution quantified via the Derenzo phantom and the quantitative accuracy achieved in a digital brain phantom are consistent with previously established benchmarks. These findings suggest that the proposed framework provides a robust and computationally efficient solution for high-resolution, quantitative reconstruction in DOI-PET systems.

Abstract
Micro X-ray computed tomography (micro-CT) enables non-destructive visualization of fine internal structures. Resolving finer details requires higher geometric magnification, typically achieved by reducing the source-to-rotation-center distance (SRD). However, short-SRD acquisition can suffer from a limited angular range due to physical interference with the X-ray source and from projection truncation when the object extends beyond the field-of-view (FOV), causing streak artifacts and structural distortions. Supervised learning-based reconstruction methods have been investigated to mitigate such artifacts but applying them to non-destructive high-magnification micro-CT is difficult because fully sampled, non-truncated reference data cannot be readily acquired without destructive sample preparation. Moreover, many existing methods are designed for 2D fan-beam geometry rather

than 3D cone-beam geometry commonly used in micro-CT. We propose an unsupervised reconstruction method that simultaneously reduces limited-angle and projection-truncation artifacts by incorporating long-SRD measurements. Long-SRD acquisition provides full-view, non-truncated projections, albeit at lower spatial resolution, complementing the high-resolution but incomplete short-SRD acquisition. By jointly using these complementary measurements, the proposed method preserves fine structural details while recovering the global object structure without requiring ground-truth images. Numerical experiments demonstrated that the proposed method reduced streak artifacts and recovered structural information outside the short-SRD FOV. To the best of our knowledge, this is the first unsupervised 3D cone-beam reconstruction method to simultaneously address both artifacts in high-magnification micro-CT.

Abstract

Time-of-flight PET (TOF-PET) enables CT-free attenuation correction (AC) through simultaneous activity and attenuation (SAA) reconstruction from emission alone. In this study, we propose a self-supervised SAA framework based on implicit neural representation. The proposed framework employs parallel hash encoders and multilayer perceptrons to learn the mapping from spatial coordinate to image space, thereby jointly reconstructing activity and attenuation maps. To further accelerate reconstruction and reduce GPU memory consumption, an ordered-subset training strategy is introduced, in which projection angles used for supervision are progressively increased during optimization. The proposed method was evaluated using analytical simulations based on a BrainWeb brain phantom with ^{18}F-FDG uptake. Compared with non-attenuation-corrected MLEM, maximum likelihood reconstruction of attenuation correction factors (MLACF) and maximum-likelihood activity and attenuation (MLAA), OSIR demonstrated improved visual consistency and quantitative accuracy. For activity reconstruction, OSIR achieved the highest PSNR of 24.62 dB and the lowest NRMSE of 5.87%, with SSIM comparable to MLAA. For

attenuation reconstruction, OSIR outperformed MLAA across all evaluation metrics. In addition, OSIR reduced the reconstruction time from 60 min to approximately 40 min. These results demonstrate that OSIR provides an efficient and robust solution for CT-free attenuation-corrected TOF-PET reconstruction, enabling accurate joint estimation of activity and attenuation maps without requiring CT images or large-scale training datasets.

Extended Field-of-View Reconstruction for Full-Ring Multi-Pinhole SPECT (#1639)

Qiao Liu, Yang Lv, Fatih N. Gür

Shanghai Jiao Tong University, Global Institute of Future Technology, Shanghai, China

Abstract

Full-ring multi-pinhole SPECT offers high sensitivity and compact detector coverage, but eFOV reconstruction remains challenging due to projection truncation, incomplete angular sampling, and reduced peripheral sensitivity, especially for large-body or off-center activity distributions.

We propose a staged deep-learning-assisted OSEM framework for eFOV recovery. The framework combines a physics-based forward model, two-stage sinogram completion, and image-domain refinement. Truncated projections are first reconstructed by OSEM as the baseline. Two residual U-Nets then sequentially restore missing detector-width information and angular views in the sinogram domain. Finally, an image-domain network suppresses residual artifacts and improves structural continuity in the eFOV region.

Simulation studies used FDG activity distributions with randomized body scaling, translation, sparse sampling, and peripheral lesion insertion. Evaluation metrics included recovery coefficient, MAE, RMSE, SSIM, and lesion-level recovery. Compared with truncated-data OSEM, the proposed method improved peripheral lesion recovery and reduced reconstruction errors. In representative cases, recovery coefficient increased from 25.9% to 96.6% at 550 mm and from 10.1% to 82.5% at 650 mm. Preliminary 3D validation also showed lower errors and higher structural similarity in axial and sagittal views. These results suggest that combining physics-based modeling with dual-domain deep learning is feasible for eFOV reconstruction in full-ring multi-pinhole SPECT. Future work will validate the framework using physical phantom and clinical data.

CT Image Reconstruction Using Deep Image Prior with VoxelMorph

(#1782)

Kensuke Hori[1], Fumio Hashimoto[2], Takeyuki Hashimoto[3]

[1] Juntendo University, Department of Radiological Technology, Bunkyo-ku, Japan; [2] University of Florida, J. Crayton Pruitt Family Department of Biomedical Engineering, Gainesville, USA; [3] Kyorin University, Department of Radiological Technology, Mitaka-shi, Japan

Abstract

Motion during scanning results in motion artifacts that distort anatomical structures in computed tomography (CT) images. In radiation therapy, planning CT scan duration are high-speed, whereas linear accelerator gantry mounted CT takes more than 15 seconds, making them more susceptible to motion artifacts. Recently, CT image reconstruction methods using supervised learning have been shown to suppress motion artifacts. However, obtaining sufficient training data is difficult because actual organ motion cannot be directly visualized. In this study, we propose an unsupervised CT image reconstruction method incorporating deep image prior and VoxelMorph (DIP-VM). The proposed method iteratively alternates between DIP-based image reconstruction and VM-based estimation of the motion vector field, in which planning CT images are leveraged as reference images. The main advantage of the proposed DIP-VM is its ability to correct patient motion using only patient-specific data, without requiring large training datasets. The proposed DIP-VM was evaluated on an XCAT phantom with cardiac and respiratory motion. Experimental results demonstrate that, using only patient-specific projection data, the proposed DIP-VM method reduces motion artifacts more effectively than the comparison methods. This study provides an effective solution for suppressing motion artifacts using only patient-specific projection data, without requiring large training datasets.

Abstract

Recent advances in diffusion models for natural image processing [1] have led to the development of several diffusion prior-based methods for medical image reconstruction [2,3,4,5,6]. For these diffusion model-based methods, balancing fidelity to the observed data (e.g., projection data) and the diffusion prior is essential. In diffusion models, low noise levels correspond to fine-grained details and therefore better preserve consistency with the observed data, whereas high noise levels correspond to coarse-grained information and rely more heavily on the diffusion prior. In our previous study, we proposed an ensemble method using multiple diffusion priors [7]. This method successfully optimized the balance between observed-data fidelity and diffusion priors in moderately sparse-view settings. However, we found that the advantage of the ensemble method decreases in extremely sparse cases with fewer than 25 views. Under such extremely sparse conditions, a diffusion prior with a large time step alone performed better than the ensemble method.

In this study, we propose a boosting diffusion model for sparse-view CT reconstruction, particularly targeting cases with severe information loss in the observed data. In the proposed method, image reconstruction is first performed using a large time step, resulting in a coarse-grained reconstruction. Subsequently, reconstruction is refined using smaller time steps, leading to fine-grained image reconstruction. We compared the proposed method with existing methods, including iterative reconstruction (IR), DPS, and SDPS, in terms of SSIM and PSNR. The results demonstrated that the proposed method outperforms the existing methods in extremely sparse-view cases with fewer than 25 views.

SPECT Reconstruction via Diffusion Sampling from a PET Image Manifold for Theranostics (#1954)

Huanzhe Wei[1], Lefteris Livieratos[1,2], George Webber[1], Andrew J. Reader[1]

[1] Kings College London, School of Biomedical Engineering and Imaging Sciences, London, UK; [2] Kings College London, Guy's and St Thomas' NHS Foundation Trust, London, UK

Abstract

Single photon emission computed tomography (SPECT) remains the standard modality for uptake verification and patient-specific dosimetry in molecular radiotherapy (MRT), however it has limited spatial resolution and noise characteristics compared to pre-therapy positron emission tomography (PET). Existing approaches that incorporate PET priors into SPECT reconstruction are often constrained by hand-crafted feature representations and suffer from inter-modality mismatch and registration-induced artifacts. In this work, we employ a conditional generative framework to enhance SPECT reconstruction toward PET-level image quality. A denoising diffusion probabilistic model (DDPM) is trained to learn the distribution of high-quality PET images. During inference, the reverse diffusion process is conditioned on measured SPECT data and CT images, enabling anatomically consistent, high-fidelity image synthesis. The method is initially assessed using 2D Zubal phantom simulations. Performance is compared with conventional maximum likelihood expectation maximization (MLEM) and kernel based methods. Both quantitative metrics and qualitative analysis demonstrate that the diffusion-based approach achieves enhanced edge preservation and superior noise suppression. The reconstructed images show closer agreement with reference data compared to MLEM and kernel based reconstructions. By avoiding explicit PET–SPECT registration, the framework mitigates spatial misalignment and associated artifacts. These results indicate that conditional diffusion sampling provides a principled and flexible approach to improve resolution and noise limitations in SPECT, with potential to improve quantitative accuracy in MRT applications.

Abstract

Diffusion models (DMs) have recently demonstrated remarkable performance in positron emission tomography (PET) image reconstruction. However, in diffusion posterior sampling, data fidelity and diffusion prior are coupled within each sampling step, which can make the balance between them sensitive to parameter selection. In this study, we propose a plug-and-play diffusion-based PET image reconstruction method (PnP-DM) that enables explicit incorporation of a DM as a prior within a penalized reconstruction. The proposed method is formulated based on Bayes' theorem and employs a half-quadratic splitting algorithm to decouple the likelihood and prior terms into penalized reconstruction and diffusion sampling. The proposed method alternates between the likelihood and prior steps, where the likelihood step penalizes deviation from the diffusion result, while the prior step is guided by the reconstructed image from the likelihood step, thereby maintaining data consistency throughout the optimization process. We evaluated the proposed method using simulated [^{18}F]FDG BrainWeb phantom datasets. The proposed method suppressed noise while preserving structural details and achieved higher contrast-to-noise ratio and contrast recovery coefficient than maximum likelihood-expectation maximization (EM) and maximum a posteriori-EM. These results suggest that the proposed PnP method provides diffusion-based reconstruction that enables more stable optimization and flexible balancing between data fidelity and diffusion prior.

List-Mode Reconstruction for Gamma-Positron Imaging (#2124)

Matthew A. Kupinski[1,2], Michael A. King[3], Shiva Abbaszadeh[4], Lars R. Furenlid[1,2]

[1] University of Arizona, College of Optical Sciences, Tucson, USA; [2] University of Arizona, Department of Medical Imaging, Tucson, USA; [3] University of Massachusetts Chan Medical School, Department of Radiology, Worcester, USA; [4] University of California, Department of Electrical and Computer Engineering, Santa Cruz, USA

This research was supported by NIH Grants: UG3EB034686 and UH3EB034686.

Abstract

We present a GPU-accelerated list-mode reconstruction framework for gamma-positron brain imaging that models PET coincidences, prompt-gamma Compton events, and triple events, in which one decay produces both detected event classes. The goal is to reconstruct the radionuclide decay distribution, rather than only the positron annihilation location, by combining the sensitivity of 511-keV coincidences with the geometric constraint from a coincident prompt gamma. The framework uses UAMonteCarlo emission and detector simulations to generate sorted list-mode events and voxelized sensitivity maps for an edge-on crossed-strip CZT geometry. The test configuration contains 690 detectors on a 30-cm-diameter ring surrounding a 24-cm water sphere and models 44Sc, including emission and transport of a 1474 keV-max positron and a 1157 keV prompt gamma. Event likelihoods are evaluated for PET-only events, two-interaction prompt-gamma events, and triple events. PET likelihoods include annihilation-photon attenuation and positron range effects; prompt-gamma likelihoods include Compton kinematics, energy deposition, detector interaction type, and attenuation; triple-event likelihoods combine PET line-of-response and prompt Compton-cone constraints. The reconstruction code computes event probabilities on the GPU and applies a list-mode maximum-likelihood expectation-maximization update. Initial consistency studies with simulated 44Sc point-source data show that PET-only and prompt-only reconstructions recover point-source locations after three iterations using 2000 events per mode, while sensitivity maps and likelihood images show the tradeoff between high-sensitivity PET/prompt events and lower-sensitivity, higher-weight triple events. These results establish machinery for combined gamma-positron reconstructions and motivate tests with triple events, mixed event-type reconstructions, and further phantom studies.

Pilot Clinical Evaluation of CT-Less PET Attenuation Correction Using Back-Scatter Coincidences on the NeuroEXPLORER System (#2352)

Zhongzhi Liu[2,1], Tiantian Li[3], Liuchun He[1], Songsong Tang[1], Yun Dong[1]

[1] Shanghai United Imaging Healthcare Co., Ltd., Shanghai, China; [2] Wuhan United Imaging Life Science Instrument Co., Ltd., Wuhan, China; [3] United Imaging Healthcare North America, Inc., Houston, USA

Abstract

Attenuation correction (AC) is essential for quantitative PET imaging and is conventionally performed using CT-derived attenuation maps. In this work, we present an initial clinical evaluation of a CT-less AC approach based on detector backward inter-crystal scattered (BKS) coincidences on the NeuroEXPLORER (NX) PET/CT system. Two patient datasets were acquired with a full-energy-window protocol that preserved standard emission coincidences, BKS events, and (^{176})Lu background events within the same list-mode dataset. For each patient, three reconstruction pipelines were compared: CT-AC+OSEM, Lu-AC+OSEM, and BKS-AC+OSEM. Results showed that, in the higher-activity case, Lu-background data were more strongly affected by random events, leading to a noisier attenuation map, whereas the BKS-derived attenuation map showed improved quality, particularly in the skull region, and yielded PET images in closer agreement with the CT-AC reference. In the lower-activity case, BKS- and Lu-derived attenuation maps were generally comparable. A short-acquisition study further showed that BKS-derived attenuation maps remained reasonably consistent for acquisition times of 5 min or longer. These results indicate that BKS-based AC is a promising direction for CT-less PET attenuation correction and warrants further evaluation in larger studies.

Abstract

In this work, we propose an unrolled Block Sequential Regularized Expectation Maximization (BSREM) reconstruction framework in which the gradient of the regularization term is learned using a convolutional neural network. Building on our previous work, we adopt Jacobian-Free Unrolling (JFU) to enable memory-efficient training on 3D synthetic data. This training strategy backpropagates only through the final iteration of the unrolled optimization, significantly reducing memory consumption while improving training stability. We investigate the influence of relaxation strategies within the unrolled BSREM scheme and analyze their impact on convergence behavior, stability, and reconstruction quality. Experiments conducted on realistic simulated SPECT datasets and clinical ^{177}Lu-DOTATATE patient data show that JFU-based unrolling consistently outperforms classical unrolled training for an equivalent number of parameters and memory usage. Unlike classical unrolling, which requires strong relaxation to ensure stable training, JFU achieves optimal performance with weak or no relaxation. Excessive relaxation is shown to be suboptimal, leading to reduced quantitative accuracy. Quantitative evaluations demonstrate improvements in both global image quality and organ-level activity accuracy compared to OSEM and conventional BSREM with a Relative Difference Penalty prior. As observed in our previous study using Green's one-step-late algorithm, the proposed approach may introduce over-separation artifacts between regions of low and high activity. This behavior appears intrinsic to learning the regularization gradient rather than to the unrolling strategy itself. Overall, this work highlights the advantages of Jacobian-Free Unrolling for scalable and stable learning-based SPECT reconstruction and provides insights into the role of relaxation in unrolled optimization schemes.

Abstract

The Multiple Emission Tomography (MET) detector, a single-layer ring of LYSO:Ce scintillators, offers a versatile imaging platform combining Positron Emission Tomography (PET) with collimator-free Compton-mode Single-Photon Emission Computed Tomography (SPECT). However, Compton reconstruction for single-layer cylindrical geometries remains a major challenge due to high data dimensionality and a dense system matrix. In this work, we present a GPU-accelerated reconstruction framework based on List-Mode Ordered Subset Expectation Maximization (LM-OSEM). Building on the open-source CoReSi library, our framework introduces several contributions. i) High-Performance Architecture: we implement a vectorized PyTorch pipeline with fused broadcasting and event batching. This approach achieves O(batch size · voxels) peak GPU memory occupancy, enabling the processing of massive datasets. ii) Advanced Physics Modeling: we introduce a system matrix that incorporates a per-event Angular Resolution Measure (ARM). This model integrates Doppler broadening, energy resolution, and detector spatial resolution, allowing for optimal event weighting and noise suppression. iii) Geometry-Specific Sensitivity: we propose a novel sensitivity model tuned for the MET cylindrical geometry, accounting for solid-angle coverage and LYSO self-absorption.The framework is validated through Monte Carlo simulations of the MET prototype. We evaluate spatial resolution and noise on reconstructed images from 511 keV to 1 MeV. Spatial resolutions between 5 mm and 10 mm are achievable, confirming MET's potential for imaging high-energy exotic nuclei inaccessible to conventional gamma cameras. This work provides a scalable, fast, and physically accurate foundation for next-generation multi-modal molecular imaging.

Abstract

Total-body positron emission tomography (TB-PET) provides significantly improved sensitivity, enabling ultra-short time framing for dynamic imaging. However, the resulting low count statistics lead to increased noise and unstable time activity curves (TACs), limiting quantitative accuracy. We investigate a kernel-based reconstruction approach within a list-mode (LM)-derived synthetic framework, where a vendor reconstruction is forward projected through an event-specific LM system matrix to generate synthetic data, implicitly includes attenuation, normalisation, scatter, and randoms effects while enabling flexible algorithm design.

Spatial, temporal, and spatio-temporal kernels are evaluated for short-frame FDG data acquired on a Biograph Vision Quadra system, with features constructed from multiple dynamic intervals. Reconstructions are compared with a 10x higher count vendor reference images using spatial and temporal PRMSE. Spatially, the spatio-temporal kernel achieves the lowest error. In addition, we demonstrated that kernel methods benefit from larger neighbourhoods resulting in improved visual quality compared to synthetic PET. This was computationally feasible on consumer hardware by using region-of-interest specific reconstructions.

These results demonstrate that LM-derived synthetic kernel reconstruction provides a flexible framework for incorporating spatial and temporal priors in TB-PET. While performance is currently limited by kernel parameter selection, the observed improvements in spatial and temporal behaviour indicate strong potential for optimisation through tuning the kernel strength and feature vector design.

Abstract

Positron emission tomography provides functional images from two-photon coincidences. In human tissue, approximately 40% of annihilations are preceded by positronium formation, of which the ortho-positronium component partially decays into three photons [1]. This three-photon channel carries additional information about the local micro-environment [1], including the three-to-two-photon yield ratio as a potential diagnostic marker [3,2], and its exploitation does not require a prompt photon, making it compatible with standard radionuclides such as FDG. We propose the Three-Photon Bayesian Imaging of Ortho-Positronium algorithm, a novel event-by-event reconstruction method formulated as a Bayesian maximum a posteriori inference problem, which unifies time-based trilateration [4], energy-based reconstruction [3], and a physics-informed prior derived from the quantum electrodynamics description of ortho-positronium decay [5-6] within a single probabilistic framework. Monte Carlo simulations modelled after the Siemens Biograph Quadra scanner [7] demonstrate an improvement of a factor of two over time-based trilateration and by an order of magnitude over energy-based reconstruction. The proposed approach is compatible with existing scanners capable of registering three-photon coincidences, broadening its applicability beyond positronium lifetime imaging to standard clinical radionuclides.

Abstract

^{90}Y bremsstrahlung SPECT imaging remains challenging due to its broad continuous energy spectrum. In this study, we proposed and evaluated a novel event-by-event energy-dependent list-mode reconstruction algorithm for quantitative ^{90}Y bremsstrahlung SPECT. To enable real-time and reasonably accurate energy-dependent collimator-detector response modeling, we proposed and incorporated a True Half-Width method into the list-mode reconstruction framework. Monte Carlo simulations were performed using three energy windows: 90-160 keV, 105-285 keV, and 90-400 keV. Quantitative evaluation was performed using contrast recovery coefficient and background variability. Compared with projection-based reconstruction, list-mode reconstruction achieved the best quantitative performance using the 90-400 keV energy window, owing to accurate event-level energy-dependent system matrix modeling over the broad continuous energy spectrum. These results demonstrate that event-by-event energy-dependent list-mode reconstruction is essential for improving the quantitative accuracy of ^{90}Y bremsstrahlung SPECT.

Evaluation of Cash C as a Cost Function for xSPECT Conjugate Gradient (#2962)

Francesc Massanes, Alexander H. Vija

Siemens Medical Solutions, MI SPECT Research, Hoffman Estates, USA

Abstract

xSPECT CG (Conjugate Gradient) SPECT reconstruction uses the Mighell Chi-Square (χ^2) statistic as its optimization cost function [3]. While effective under standard count conditions, the Mighell statistic is known to be suboptimal when Poisson statistics are poorly approximated at low counts. The Cash C statistic offers an alternative formulation derived from a modified chi-square for Poisson data, better suited to low-count regimes[2]. This work evaluates Cash C as a direct replacement for Mighell χ^2 in xSPECT CG, assessing resolution-noise trade-offs across count levels using a standard phantom. Resolution was quantified using a metric based on the approach described in [1], further developed here to handle arbitrary source-to-background contrasts. Cash C consistently achieved better noise properties at equivalent resolution compared to Mighell χ^2, with both algorithms converging to similar minimum resolution values 16.4 mm FWHM) at high update steps for the 8 mL sphere, confirming no loss of performance at high-count conditions. These characteristics are particularly relevant for clinical applications with limited count statistics, including cardiac SPECT [4] and emerging theranostic radiopharmaceuticals.

Investigation of Ray Driven Collimator Detector Response Model for Multi-Photopeak SPECT Reconstruction (#3098)

Thibaut Merlin[1,3], Baptiste Laurent[1,3], Dimitris Visvikis[3]

[1] CHRU de Brest, Brest, France; [2] INSERM UMR1101 LaTIM, Brest, Germany; [3] LaTIM INSERM UMR 1101, Bâtiment 1, premier étage CHRU Morvan, Brest, France

Abstract

In SPECT imaging, accurate modeling of the collimator–detector response (CDR) function is essential for improving image resolution and quantitative accuracy. The CDR profile depends on several physical factors whose modeling can be complex and computationally demanding, particularly for multi-photopeak datasets, since the CDR, photon attenuation, and Compton scattering are energy dependent. In this work, we investigate the modeling of the CDR function using profiles generated through Monte Carlo simulations and its incorporation into the reconstruction process using a multi-line projector approach.
Monte-Carlo simulations were processed in order to generate CDRs of a SPECT intevo system with MELP collimator using 177Lu point sources located at different distances of the imaging system. These data were combined to generate CDR reponses for both 208kev and 113kev photopeaks. A multi-lines projector was implemented to integrate these profiles and processes the corrections specific to each photopeak. Simulations of NEMA IQP phantom was conducted to assess the proposed implementation, as well as phantom data acquired with the same system and variable source to collimator distance for each projections.
The proposed model improves the CRC-versus-noise trade-off as well as the overall image quality. Although increasing the number of projection lines enhances the signal-to-noise ratio, the evaluated metrics show limited improvement beyond a certain number of lines. These results suggest that for the studied acquisition and reconstruction setup, a reduced number of lines per detector channel may be sufficient to accurately model the CDR while limiting the computational cost of the reconstruction process.
Ongoing work includes the evaluation of the proposed implementation with different collimator geometries exhibiting various septal penetration and scattering characteristics. Future investigations will focus on simulations involving high-energy photon-emitting radionuclides.

Deep Kernel Gaussian Process Prior for Robust, Anatomically Guided Radiation Image Reconstruction (#3129)

Jaewon Lee, Javier Caravaca

Lawrence Berkeley National Laboratory, Applied Nuclear Physics (ANP), Berkeley, USA

Abstract
Newly emerging radiation imaging modalities—such as Compton camera imaging of alpha-emitting radiopharmaceuticals, positronium lifetime imaging, and dynamic PET imaging—frequently operate under count-starved, low signal-to-noise ratio (SNR) conditions, where the conventional maximum likelihood expectation maximization (ML-EM) algorithm is prone to severe overfitting. While recent neural network-based reconstruction methods have achieved impressive results, they require large amounts of task-specific training data, often neglect physics constraints, and largely lack principled uncertainty quantification frameworks.
In this work, we propose a Bayesian image reconstruction algorithm incorporating a Gaussian process (GP) prior with a neural network-based kernel, combining the robustness and principled uncertainty quantification of the GP framework with the representational flexibility of neural networks. The proposed method is highly robust against measurement noise, naturally incorporates physics constraints through the forward model, supports anatomically guided reconstruction through co-registered structural imaging data, and provides a full posterior covariance

characterization via variational inference. We demonstrate significant improvement in reconstruction quality over the conventional ML-EM algorithm alongside meaningful uncertainty estimates.

ChameleonIQ: Bridging NEMA NU-2 and NU-4 Standards through Automated Image Analysis (#1243)

Edwing Y. Ulin-Briseño, Santiago Jiménez-Serrano, Antonio J. Gonzalez

CSIC-Universitat Politècnica de València, The Institute for Instrumentation in Molecular Imaging (I3M), Valencia, Spain

Abstract

Quantitative positron emission tomography (PET) requires standardized and reproducible image quality assessment to ensure comparability across scanners, protocols, and institutions. However, current workflows for NEMA-based evaluation often rely on manual region-of-interest (ROI) definition and fragmented analysis tools, limiting reproducibility and scalability. In this work, we present ChameleonIQ, an open-source, configuration-driven framework for automated PET image quality assessment. The platform supports both NEMA NU-2 2018 and NEMA NU-4 2008 protocols within a unified pipeline, providing automated ROI definition, deterministic metric computation, and structured reporting. Validation was performed using standardized IEC Body and NU-4 IQ phantoms. For the NEMA NU-2 protocol, contrast recovery ranged from 29.5% (10 mm sphere) to 55.1% (37 mm sphere), with background variability maintained between 6.1% and 7.0%. For the NEMA NU-4 phantom, recovery coefficients exceeded 0.8 for rods larger than 3 mm. The framework demonstrated high quantitative fidelity, achieving an average error in hot rod recovery of only 3.9% compared to reference manual evaluations. By providing a semi-automated pipeline that maintains this high precision while removing operator bias, ChameleonIQ facilitates efficient protocol optimization and multi-center benchmarking.

Position-, direction- and contrast-dependent measurement of MLEM-reconstructed PET resolution using a 3D-printed cube (#1967)

Santiago Alvarado Orozco[1], Matthijs Sevenois[2], Georg Schramm[1]

[1] KU Leuven, Department of Imaging and Pathology, Leuven, Belgium; [2] UZ Leuven, Division of Nuclear Medicine, Leuven, Belgium

Abstract

The reconstructed spatial resolution of a PET image is determined by both intrinsic scanner properties and the chosen reconstruction algorithm. Standard NEMA measurements use point sources reconstructed with FBP and therefore mainly characterize the scanner. They are thus suboptimal for predicting the resolution of images reconstructed with MLEM and point-spread-function modeling, as is common in clinical practice.

We propose a 3D-printed resolution cube with an off-center inner compartment which, combined with a mid-acquisition phantom flip and a single reconstruction, produces sharp edges at finite (2:1) contrast along three orthogonal directions. Position-, direction- and contrast-dependent edge and line spread functions (ESFs, LSFs) are then extracted using smoothing-spline fits. As a proof of concept, the method is applied to the NeuroExplorer brain PET system at the isocenter and 10 cm off-center, with and without depth-of-interaction (DOI) modeling.

The LSFs are non-Gaussian with pronounced negative side lobes. With DOI, the resolution is approximately 2.5 mm FWHM in all directions at both positions; without DOI it degrades radially to about 4 mm at 10 cm off-center. Notably, differences between finite and infinite contrast are small in most configurations.

The method provides a position-, direction- and contrast-dependent characterization of PET resolution from clinically reconstructed images and complements NEMA point-source values for image quality comparison, harmonization and partial volume correction.

Evaluation of Motion Correction Methods on the NeuroEXPLORER Using Multi-Tracer Human Data (#2130)

Jiazhen Zhang, Tianyi Zeng, Yifan Hu, Kathryn Fontaine, Tommaso Volpi, Takuya Toyonaga, Richard E. Carson

Yale University, New Haven, USA

Research funding support: U01EB029811.

Abstract

Accurate motion correction is critical for dynamic brain PET, particularly on the high-resolution NeuroEXPLORER (NX), where residual head motion can blur focal targets and bias time-activity curves (TACs). We evaluated multiple motion correction (MC) strategies using 17 multi-tracer human NX PET scans, including no motion correction (NMC), post-reconstruction registration (PRR), registration before attenuation correction (RBA), UMT-based frame-averaged correction (AVG), and UMT-based event-by-event correction (EBE). Performance was assessed using qualitative image comparison and ROI-based residual TAC variability ($\%SD_{res}$) from 20-70 min. All MC methods reduced $\%SD_{res}$ compared with NMC. Across all tracers, subjects, and ROIs, EBE achieved the lowest residual variability (1.40 ± 1.27%), followed by PRR (1.79 ± 1.49%), RBA (1.94 ± 1.64%), AVG (2.01 ± 1.63%), and NMC (4.68 ± 4.26%). Poisson noise-floor analysis further showed that residual motion effects were tracer- and count-statistics-dependent. Overall, UMT-based EBE provided the most effective reduction of residual motion effects in dynamic NX brain PET.

A Clinically Viable, Scalable Implementation of Monte Carlo Scatter Correction for PET/CT (#2119)

Danielle Zeltser[1], Ester Hait-Fraenkel[1], Xuezhu Zhang[2], Michal Edelstein[1], Gali Elkin-Basudo[1], Yaniv Mizrachi[1], Yariv Grobshtein[1]

[1] GE HealthCare, Molecular Imaging, Haifa, Israel; [2] GE HealthCare, Molecular Imaging, Waukesha, USA

Abstract

Monte Carlo scatter correction is well established as a highly accurate approach for scatter estimation in PET/CT imaging. It demonstrates superior robustness compared with model based scatter estimation methods, particularly under extreme variations in activity distribution and in the presence of patient motion, conditions under which model based approaches often produce artifacts. Despite these advantages, Monte Carlo scatter correction is computationally intensive, and does not inherently account for out-of-field scatter. In this work, we address both limitations and propose an implementation suitable for integration into routine clinical workflows. A multi-GPU implementation, as well as parallel processing with efficient data streaming significantly reduce the processing time. To handle out-of-field scatter, we separately handle regions where information about out-of-field distribution is known, and can be used for a highly precise estimation. In regions where out-of-field information is inaccessible, the effect on scatter is approximated by the measured data, while ensuring a smooth transition in which the high-accuracy region governs the final estimate. Our approach is scalable and robust across system designs ranging from a standard axial field-of-view to a long axial field-of-view, each presenting distinct considerations for scatter estimation. We demonstrate the effectiveness of our method using phantom and clinical data.

Abstract

In simultaneous PET&SPECT imaging, PET-induced down-scatter contaminates SPECT data, degrading image quality and quantitative accuracy. This study presents a correction method that estimates PET down-scatter based on PET source modeling and corrects contaminated SPECT data to suppress PET interference.

A PET&SPECT simultaneous imaging system is modeled using GATE Monte Carlo simulation. The system adopts a dual-head detector rotating around the field of view. An image quality phantom consisting of background region, cold region, and multiple PET and SPECT hot regions is simulated to evaluate cross-modality interference. PET and SPECT activities are modeled using 511 keV annihilation photons and 140 keV gamma photons. A uniform PET activity distribution is simulated to establish a voxel-wise PET down-scatter contribution model. The actual PET activity distribution is obtained from reconstructed PET images, and the corresponding down-scatter components are estimated from the model and subtracted from the SPECT projections.

Experimental results demonstrate that PET-induced down-scatter significantly degrades SPECT projections and reconstructed image quality. The auxiliary energy window (AEW) method partially mitigates this degradation, while the proposed method achieves more effective suppression, yielding images closer to a pure SPECT reference. Quantitative evaluation shows that the proposed method outperforms AEW in terms of spillover ratio and contrast, confirming its effectiveness in simultaneous PET&SPECT imaging.

Abstract

A dedicated brain positron emission tomography (PET) system utilizing multi-resolution depth-of-interaction (DOI) detectors is under development at Shenzhen Bay Laboratory. These detectors employ variable-pitch, multi-layer scintillators to optimize intrinsic spatial resolution and coincidence timing resolution while minimize parallax errors. However, the multi-resolution architecture introduces structural and detection heterogeneities that complicate quantitative image reconstruction. This study proposes an extended quantitative correction framework to address these challenges. We adapted standard component-based normalization (CBN) and single scatter simulation (SSS) via sub-layer-based geometric modeling to achieve layer-specific normalization and scatter correction. Specifically, a 3D fan-sum method was implemented to calculate crystal efficiencies by treating lines of response (LORs) within shared DOI layers as independent subsystems. Furthermore, a likelihood-based optimization framework was formulated to derive layer-specific scatter multipliers, compensating for detection biases caused by inter-layer shielding and axial sensitivity fluctuations. The framework was validated using GATE simulations. Ablation studies on uniform cylinder data confirmed the necessity of the integrated correction suite for spatial uniformity. Quantitative evaluation of a custom IQ phantom yielded contrast recovery coefficients (CRC) of 84.53%–65.13% and background variability (BV) of 1.69%–3.07% for spheres ranging from 37.0 to 13.0 mm. Reconstructed Derenzo phantom images resolved 1.0 mm rods at both central and off-center positions, validating its high spatial resolution. Finally, digital brain phantom studies indicate that the system's imaging performance is visually comparable to the NeuroEXPLORER benchmark.

Intra-frame motion correction for dynamic PET using mutual information-based registration (#2653)

Simon Noë[1], Matthew Spangler-Bickell[2], Ahmadreza Rezaei[1], Johan Nuyts[1], Georg Schramm[1]

[1] KU Leuven, Department of Imaging and Pathology, Nuclear Medicine & Molecular imaging, Leuven, Belgium; [2] GE HealthCare, Waukesha, USA

This work was supported by a KU Leuven C2 grant (3M220301): "Motion compensation for PET in TOF-PET/CT and TOF-PET/MR brain imaging".

Abstract

Patient motion remains a challenge for dynamic positron emission tomography (PET) imaging of the brain, due to long acquisition times. Data-driven registration-based motion estimation for static PET using sum of squared differences or normalized cross correlation as alignment metric (while popular for their simplicity and generalization potential) are not suitable for dynamic PET, as they cannot handle the changing tracer distribution throughout the scan. Alternative methods for dynamic PET motion estimation rely on the availability of a good kinetic model or suitable training data for deep learning, reducing their generalization potential. We therefore propose a registration method based on mutual information that makes it suitable for dynamic PET, and included the motion estimates in a listmode reconstruction using event-by-event motion correction. We tested this approach for 3 tracers on 2 patient scans each.

Abstract

Head motion during PET data acquisition is a common source of artifact that degrades image quality and biases tracer uptake quantification. We hypothesize that motion correction improves the performance of a machine learning (ML) classifier for Alzheimer's disease versus cognitively normal subjects using brain PET images alone. A ResNet10 feature extractor combined with a Support Vector Machine classifier was applied to two cohorts encompassing a total of 301 ^{11}C-UCB-J and ^{18}F-FDG PET. On motion-corrected images, the classifier achieved AUROC of 0.96 (^{11}C-UCB-J) and 0.94 (^{18}F-FDG), with accuracy increases of 5% and 10%, respectively, when motion correction was applied. Our results highlight the critical need for efficient motion correction solutions to enable effective ML analysis of PET AD imaging.

Abstract

This work develops and evaluates CT-less data correction methods for quantitative cardiac PET by combining deep learning-based attenuation correction (DLAC) with energy-based scatter (EBS) estimation. Robustness was assessed in three human FDG studies spanning a wide BMI range (24-50 kg/m²). DLAC showed stable performance across BMI groups, with mean myocardial SUV biases below 5% relative to CT-based AC (with single scatter simulation). For a low BMI case, the DLAC+EBS method resulted in low myocardial SUV bias (mean: 1.7%, P_5-P_{95}: [–2.1%, 10.8%]) relative to standard CT-based reconstruction. To assess generalization, the DLAC model (originally trained on supine non-cardiac human data) was extended to cardiac ^{82}Rb studies in pigs using transfer learning. These pig studies served as a surrogate for evaluating whether the network could be adapted to other imaging conditions (cross-tracer, cross-species, and other patient positionings, e.g., seated cardiac imaging) with limited re-training. With limited additional pig data (n=8), relative biases in mean myocardial SUV decreased to within 2%. Overall, these findings support CT-less data correction for cardiac PET systems.

Abstract
Existing software solutions for PET quantification in neurological disorders remain fragmented and lack comprehensive end-to-end pipelines suitable for multi-site studies involving heterogeneous tracers, and scanners, including Total-Body PET systems. We present AmyPET, an open-source toolkit for automated end-to-end preprocessing and quantification of static and dynamic PET data directly from raw DICOM images. The framework supports processing in both native and MNI image spaces and integrates multiple brain atlases, motion correction, partial volume correction, and harmonised analysis within a single modular environment.
AmyPET comprises four integrated processing engines for static and dynamic PET analysis: (1) an alignment engine for moderate motion correction based on a novel displacement metric, (2) spatial normalisation and tissue segmentation, (3) regional sampling and image extraction, and (4) a post-processing engine enabling kinetic modelling, Centiloid quantification, and additional quantitative analyses, including dual-time-window acquisitions. Automated quality-control outputs are generated for all processing stages. The framework has been calibrated against the GAAIN reference datasets for amyloid PET and is extensible to tau and TSPO tracers.
Validation was performed using multiple amyloid PET cohorts, including test–retest studies, an amnestic mild cognitive impairment cohort, and the AMYPAD Prognostic and Natural History Study comprising more than 1500

scans. AmyPET demonstrated high repeatability (within-subject coefficient of variation, wCV=3.5%; ICC>0.98) and strong agreement with established clinical and research pipelines (R^2>0.96), supporting its use as a robust and scalable framework for quantitative neuroPET imaging.

SSS Optimised for Monte Carlo Scatter Estimation for PET (#3060)

Antonia Reeves[3,2], SeyedAmir ZamanPour[1], Simon Noe[1], Simon Arridge[4], Kris Thielemans[2,3]

[1] KU Leuven, Department of Imaging and Pathology, Leuven, Belgium; [2] University College London, Institute of Nuclear Medicine and the Hawkes Institute, London, UK; [3] University College London, Department of Medical Physics and Biomedical Engineering, London, UK; [4] University College London, Department of computer science, London, UK

This work was supported by the i4Health Centre for Doctoral Training, UCL and GE Healthcare. Software used in this project is maintained by CCP SyneRBI (UKRI support: EPSRC grant EP/T026693/1 and STFC through the DRI programme).

Abstract
Recent increases in computational power as well as new tools being more readily available have led to increased interest in Monte Carlo scatter estimation. However, Monte Carlo scatter simulation is still computationally expensive. This is exacerbated by the fact that model-based scatter estimation requires multiple iterations of scatter simulation and image reconstruction. We propose to combine the current clinical standard (analytic single scatter simulation and tail-fitting) with Monte Carlo scatter simulation.

Quantitative Activities Evaluation of Ac-225 and Daughter Nuclides Using the Alpha-SPECT Mini System (#3094)

Wenbo Zhao[1], Xuhan Luo[1], Ling-Jian Meng[2], Yong Du[1]

[1] Johns Hopkins University School of Medicine, Baltimore, USA; [2] University of Illinois at Urbana and Champaign, Champaign Il, Champaign, USA

This research was funded by National Institutes of Health, grant number S10OD038221. The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health.

Abstract

The Alpha-SPECT Mini system integrates SPECT imaging with CT-based attenuation correction, providing a platform for quantifying in vivo distributions of alpha-emitting radiopharmaceuticals and daughter radionuclides. In this study, three Ac-225 filled syringes with different volumes, 0.5, 4.2, and 18.0 mL, respectively, were scanned with Alpha-SPECT Mini. The ground truth activities were[YD1] 26.12 μCi, 21.62 μCi, and 18.80 μCi from the smallest to the largest syringe, respectively. SPECT listmode acquisition was performed for 20 minutes for each syringe, together with an 80 kV CT scan for attenuation correction. SPECT images were reconstructed for the following photopeaks: 100 keV for Ac-225, 218 keV for Fr-221, 440 keV for Bi-213, and 117 keV for Tl-209. Activities of Ac-225 and these daughter radionuclides, were then estimated from SPECT images using CT defined ROIs and compared with ground truth.

The results showed that quantification accuracy varied with the radionuclides and syringe sizes. Fr-221 and Bi-213 showed relatively lower errors (<5%), while Ac-225 and Tl-209 exhibited larger deviations. The higher errors likely due to the low abundance of low energy (100 keV for Ac-225 and 117 keV for Tl-209) photopeaks and interference from downscatter and collimator penetration from high energy photons. Tl-209 also exhibited larger deviations with a size-dependent trend, suggesting sensitivity to source geometry and scatter correction. Overall, the Alpha-SPECT Mini system showed potential for quantitative imaging of Ac-225 and daughter radionuclides. Future work includes further calibration and implementation of scatter correction.

Abstract
PETcoil Gen II is a novel MRI-compatible time-of-flight (TOF) PET system for simultaneous PET-MRI brain imaging. Current calibration uses an annulus phantom to correct time skew on a per line-of-response (LOR) basis, leading to a large number of correction factors (order n^2). We propose a convex-optimization calibration method to calculate and store per-channel (order n) time skew offsets using rod phantoms. We evaluate the method using simulated annulus and rod phantoms with known applied skew offsets and point-source validation. The proposed per-channel approach achieves a mean absolute timing error of 19.9 ps (annulus-based) and 18.8 ps (rod-based) compared to 142 ps for the per-LOR method. When applied to point-source correction, the proposed approaches improve coincidence time resolution (CTR) performance by +18.7\% and 13.4\% using annulus and rod phantoms respectively, whereas the per-LOR approach resulted in a -70.0\% degradation relative to uncorrected data. Results demonstrate improved calibration accuracy and robustness in using rod-based phantoms. Future work will validate these methods experimentally and assess the quality of reconstructed images.

Abstract

Digital breast tomosynthesis (DBT) improves lesion detection compared with 2D digital mammography (DM), but its large number of reconstructed slices leads to increased reading time and workload for radiologists. As a potential solution, thick-slab image generation can be used to combine adjacent reconstructed slices into fewer representative slab images. However, conventional slab generation methods typically rely on simple slice-combination strategies, such as maximum intensity projection (MIP) or average intensity projection (AIP) of adjacent slices, which may reduce image sharpness and obscure diagnostically relevant details. To overcome these limitations, we propose a new thick-slab image generation method. For each slab, the proposed method adaptively blends a representative slice with the corresponding MIP image. The representative slice is selected from the DBT slices within the slab based on linear structure information obtained using the oriented bins method. The blending map is generated by applying a 1D high-pass filter to the MIP image along the X-ray source travel direction. Using a numerical phantom, the proposed method was compared with conventional MIP- and AIP-based slab generation methods and showed improved image sharpness and structural preservation. These preliminary results suggest that the proposed thick-slab image generation method has the potential to reduce DBT review time by decreasing the number of images to be reviewed without substantial loss of diagnostically relevant information.

STIR is partially maintained by CCP SyneRBI which is funded by the EPSRC grant EP/T026693/1 and by STFC through the UKRI Digital Research Infrastructure programme

Abstract

STIR is a widely used open-source framework for PET and SPECT image reconstruction; here we explored PyTorch as an alternative array backend for STIR. We replaced the STIR arrays with a tensor-based variant while preserving the existing reconstruction framework and backwards compatibility. Correctness was assessed using existing and newly developed unit tests. Performance was evaluated with dense arithmetic benchmarks, stir_timings, and stir_math. For image-based operations, the tensor backend accelerated in-memory processing, with the largest gains observed for larger volumes. In projection-data workflows, initial performance was limited by layout-conversion and storage overhead, but targeted optimization substantially reduced these costs. In projection-data stir_math tests, the Torch-backed implementation was faster than the native STIR Array backend in end-to-end execution, with gains of roughly 7% to 23% depending on the operation. Initial GPU benchmarking further showed that the tensor backend can exploit consumer GPU hardware for dense arithmetic, achieving an approximate 3.7x speedup over CPU in the tested workload. However, projector-style kernels based on sparse, irregular scalar access did not yet benefit consistently from direct backend substitution, indicating that these critical paths require further redesign.

Abstract

Accurate quantification of pulmonary PET activity is often limited by spill-in contamination from adjacent tissues. Although reconstruction-based partial volume correction techniques effectively reduce resolution-related blurring, residual spill-in can remain significant in pulmonary analysis due to respiratory motion and proximity to high-uptake extrapulmonary structures. Post-reconstruction correction methods often assume homogeneous activity within clearly defined anatomical compartments, assumptions not satisfied in inflammatory whole-lung volumes. As a result, manual refinement of the lung boundary is often necessary but is also time-intensive. Here, we compare three automatic post-reconstruction spill-in correction strategies in 18F-FDG PET scans of tuberculosis-infected macaques, using manually refined lung masks as a reference. Two methods directly adjust PET values within the lung: the first estimates spill-in from local background activity, while the second applies a more conservative correction using extrapulmonary hotspots. The third method automates conventional morphological mask refinement by adjusting the lung boundary. The value-based spill-in correction methods achieved higher agreement with manual refinement (mean log ratio 0.032 and 0.116) but showed greater sensitivity to boundary perturbation, whereas morphological correction showed lower boundary sensitivity but systematically underestimated uptake (mean log ratio -0.408). These findings suggest that localized spill-in correction methods may provide a practical alternative to manual mask refinement in 18F-FDG PET pulmonary imaging by reducing extrapulmonary contamination while preserving anatomical boundaries.

Abstract

Wearable brain PET enables neuroimaging during free movement, but head motion causes severe degradation. Compact scanners are particularly sensitive because their small detector rings (~100 mm) amplify angular displacements at the event level. We compare five data-driven motion correction approaches on a wearable scanner using programmed Derenzo phantom motion, with all-data 3-DOF control groups isolating event retention from algorithmic accuracy. The hybrid phase-correlation with mutual-information 6-DOF method achieves the best resolution–noise trade-off—FWHM 4.68 mm vs. 5.42 mm for all-data 3-DOF and 15.15 mm for uncorrected—with SNR of 4,586. Results confirm that 6-DOF event-level correction is essential for compact-geometry wearable PET.

This work was supported by the National Research Foundation of Korea(NRF) grant funded by the Korea government(MSIT)(RS-2024-00347270).

Abstract

Radiographic image quality is degraded by X-ray scatter, which reduces contrast and obscures fine anatomical structures, especially in thick body regions. This study proposes a calibration-free software scatter correction method for radiographic imaging based on pixelwise alpha blending of dark channel prior and bright channel prior. The observed radiograph was modeled as attenuated primary radiation plus additive scatter. Scatter intensity was estimated using self-guided filtering, and transmission maps were generated from dark and bright channel priors. Because dark channel prior can fail in bright anatomical regions such as bone, an attenuation-based alpha weight was used to adaptively combine the two transmission maps. The restored radiograph was obtained using the estimated scatter intensity and refined transmission map. The method was evaluated using in vivo animal radiographs acquired with a mobile radiographic imaging system at 100 kVp and 40 mA. Rabbit, beagle dog, and mixed-breed dog images were used to assess performance across different body sizes and scatter conditions. Image quality was compared among the observed image, dark-channel-prior-only correction, and the proposed alpha-blended correction. The proposed method improved anatomical visibility and reduced overcompensation artifacts in bright bone regions. The contrast-to-noise ratio increased from 0.85 in the observed image and 1.78 with dark-channel-prior-only correction to 2.18 with the proposed method. These results demonstrate that pixelwise blending of dark and bright channel priors can improve radiographic contrast and fine-structure visibility without additional hardware or calibration.

Abstract

Timepix4 hybrid pixel detectors, originally optimized for single-particle tracking applications, are increasingly attractive for medical X-ray imaging owing to their large area (~7 cm2), 4-side buttability and appreciable data-driven throughput (3.6 × 106 hits/mm2). Adapting them to imaging workflows, however, demands a substantial shift in data handling. A notable challenge is presented by coping with intensity-dependent data rates, and efficiently aggregating hits and clusters into fixed-size structures under heavy loads. This contribution describes a collection of stackable software tools that adapt an established event-driven tracking framework for Timepix-based systems to X-ray imaging, organized over a modular processing pipeline. The presented platform includes energy-band splitting of hit and cluster streams and corrections for commonly seen effects: internal fluorescence of CdTe sensors, per-pixel high-energy correction, cluster-volume energy loss, non-uniform flat field response and beam hardening. The composition order of these operations is treated as a user-driven parameter, permitting construction of dedicated processing workflows depending on the imaging task at hand. Fluorescence recovery, high-energy correction, and cluster volume correction are already operational and have been tested experimentally; the remaining features are under active development. The full platform is expected to be applied to representative medical imaging tasks over the summer of 2026, with quantitative results to be presented at the conference.

A phase shifting method to provode three dimensional position information of an incident gamma ray (#2533)

Shuwei Zhao, Hiroyuki Takahashi

The university of Tokyo, Graduate school of Engineering, Bunkyo City, Japan

Abstract

Phase-shifting sub-pixel sampling can improve the spatial granularity of compact gamma-ray detector modules without using analog charge sharing or Anger-logic interpolation.In this work, the phase-shifting concept is extended toward depth of-interaction (DOI) estimation by combining controlled detectordisplacement with double-sided MPPC readout. A monolithic scintillator is coupled to two readout sides, denoted as A and B, and the DOI-sensitive observable is defined by the signal ratio $A/(A + B)$. The detector is translated laterally by 1 mm steps relative to a narrow slit so that the effective irradiation position changes within the scintillator thickness. Coincidence signals are then analyzed using A-B correlation plots. The measured slopes vary systematically from the B-side region to the A-side region,
indicating that interaction depth information is preserved in the double-sided signals. These results demonstrate the feasibility of integrating phase-shifting sampling with DOI estimation for compact SPECT or Compton camera detector modules.

Abstract

Micro-single photon emission computed tomography (µSPECT) is constrained by an inherent sensitivity-resolution trade-off imposed by the collimator. High-sensitivity collimators mitigate statistical noise but blur spatial details, whereas high-resolution collimators limit count sensitivity, thereby amplifying noise. To bridge this trade-off and overcome both low sensitivity and poor resolution, we propose and compare three frameworks for joint µSPECT denoising and super-resolution: a single Joint U-Net, a sequential Cascade U-Net, and a Dual-Encoder U-Net utilizing task-specific encoders and a shared decoder. Models were trained on paired mouse datasets to map noisy low-resolution acquisitions (10-50% of standard counts) to high-resolution targets, acquired with two different collimators. The Dual-Encoder architecture most effectively balanced the competing objectives of noise suppression and edge preservation by extracting distinct representations before merging. Compared to the input, the model achieved a 32% reduction in overall RMSE and an 8% improvement in SSIM. Furthermore, it demonstrated superior resolution recovery relative to the Joint and Cascade approaches, reducing edge map and spectral errors by 27% and 21% compared to the input, respectively. Visually, it was the only model capable of resolving rod peaks in a Derenzo phantom. This approach enables significant reductions in acquisition time or dose while maximizing precision for preclinical quantification.

Self-supervised PET Denoising Based on the Noise2Noise Principle (#2820)

Sacha Bouchez-Delotte[1], Jérôme Idier[1], Simon Stute[2], Clément Huneau[1]

[1] Nantes Université, École Centrale de Nantes, CNRS, LS2N, Nantes, France; [2] CHU Nantes, Serive de médecine nucléaire, CRCI2NA, INSERM UMR 1307, Nantes, France

Abstract

PET reconstruction aims to transform raw sinograms data into images using analytical, iterative or deep learning approaches. In addition to the ill-posedness of the problem, inherent Poisson noise in sinograms makes the problem more difficult, especially in low-dose contexts.

Using deep learning for image denoising and reconstruction has shown promising performances. However, supervised training requires large sets of paired data with corrupted images and their associated ground truth, which is hard or even impossible to acquire in the medical field, especially in emission tomography.

In this work, we adapted Noise2Noise, a self-supervised framework, to PET imaging in order to learn how to denoise images from noisy measurements only.

Python Integration in CASToR: Application to the End-to-End DIP-Based PET Reconstruction (#2865)

Nasrin Taheri[1], Maxime Toussaint[1], Alexandre Merasli[3], Simon Stute[1,2]

[1] CRCI2NA, INSERM UMR 1307, Nantes University, Nantes, France; [2] Nuclear Medicine Department, Nantes University Hospital, Nantes, France; [3] Hematology Biology, Nantes University Hospital, Nantes, France

Abstract

Modern PET reconstruction methods increasingly rely on advanced optimization strategies and deep learning-based priors. However, integrating such approaches into established reconstruction toolkits remains challenging due to limited interoperability with high-level programming environments. In this work, we present a framework that enables Python integration within the CASToR reconstruction platform, allowing direct interaction between C++

reconstruction routines and Python-based modules. As a proof of concept, we implemented an end-to-end PET reconstruction approach incorporating the Deep Image Prior (DIP) and a forward projection model. This example illustrates how the proposed integration facilitates the use of modern Python libraries for deep learning within a physics-based reconstruction framework. This work opens the door to rapid prototyping and deployment of advanced reconstruction algorithms within CASToR using the Python ecosystem.

Abstract

High-resolution PET systems require accurate DOI calibration to reduce parallax errors. Conventional DOI calibration methods rely on lateral detector access and collimated irradiations, resulting in complex and time-consuming experimental setups. In this work, we investigated the use of an analytical DOI model and a multilayer perceptron (MLP) network for DOI calibration and DOI resolution estimation using only detector front-face irradiations. The methods were evaluated on a dual-ended-readout 4 × 4 detector panel. Crystal-wise DOI calibration estimates obtained using the analytical model and the MLP showed good agreement with ground-truth measurements, with median calibration RMSE values below 0.6 mm and 0.7 mm, respectively. However, the MLP yielded superior DOI resolution prediction, with consistent mean DOI resolution estimates of approximately 2.0 mm.

Abstract

Radiomics is used to extract high-dimensional features from medical images such as computed tomography. However, radiomic features are susceptible to acquisition protocols in a multi-center setting. This results in domain shift in data distribution even when the patient anatomy is the same. This can increase intraclass variability and lead to algorithms learning protocol-specific artifacts rather than clinically relevant imaging information. In this work, we developed a virtual imaging trial (VIT) of pancreatic ductal adenocarcinoma (PDAC) patients scanned across multiple scanners and protocols to quantify protocol-induced radiomic variability post harmonization. A virtual patient cohort of 50 patients was generated using the XCAT. PDAC tumors extracted from clinical cases were implanted in individual virtual patients. DukeSim was used to simulate Siemens clinical scanners. For each scanner, two clinically representative acquisition protocols were designed by varying tube current, pitch, and reconstruction kernel. Radiomic features were extracted from tumor regions and harmonized using scanners and protocols as batch effect. Scanner and protocol dependency of each feature was assessed using Wilcoxon and Kruskal–Wallis tests, respectively. Feature robustness was quantified using intraclass correlation coefficient. Protocol-related batch effects were prominent in the non-harmonized data, with 85.98% of radiomic features dependent on protocols. Protocol-based CovBat achieved the best overall performance, reducing protocol-dependent features to 19.63% and increasing reproducible features by 3.8% post harmonization. Therefore, the proposed VIT-based framework can be used to evaluate harmonization methods and assess radiomic feature robustness before developing clinical decision-support models.

Abstract

Prostate-specific membrane antigen (PSMA) PET/CT enables standardized quantitative tumor burden assessment, yet routine SPARC-aligned metrics, molecular tumor volume (MTV), total lesion activity (TLA), and total lesion fraction (TLF), show limited predictive value for early biochemical response. Allometric scaling laws (TLA ∝ MTV^β) govern metabolic activity superlinearly (β > 1) across multiple cancers, but their application to PSMA PET outcome prediction remains unexplored. We hypothesized that each patient's deviation from the cohort-level scaling line, the Distance from the Scaling Law (DSL), encodes biologically distinct information beyond raw burden metrics and predicts PSA50 biochemical response (PCWG3: ≥50% PSA decline). In 103 prostate cancer patients with PSMA PET/CT and paired PSA measurements from a real-world clinical cohort, we fitted the allometric law (TLA = α × MTV^β) and computed per-patient DSL residuals. The cohort exhibited a superlinear scaling law: TLA = 0.574 × MTV^1.157 (R^2 = 0.782, $p < 0.0001$) consistent with literature values (β ≈ 1.22–1.28). DSL ranked 4th among 12 candidate features in univariate discrimination (AUC = 0.668), outperforming standard SPARC burden metrics including TLF (0.589), TLA (0.588), and MTV (0.523). Non-responders showed lower DSL than responders (mean −0.243 vs +0.018; rank-biserial r = 0.336), indicating hypoactive PSMA uptake relative to tumor volume as a failure signature. Nine cost-sensitive classification strategies under 5-fold stratified cross-validation reached balanced accuracy of 0.57–0.64, constrained by extreme class imbalance (93.2% responders). These findings establish DSL as a physics-grounded, automatically computable biomarker that outperforms conventional burden metrics and is deployable within SPARC workflows.

A Cucker–Smale Flocking Model for Edge-Aware Medical Image Analysis (#3017)

Amirreza Hashemi, Hamid Sabet

Harvard Medical School/Massachusetts General Hospital, Radiology Department, Boston, USA

This work was supported in part by NIH grant R01EB034785.

Abstract

We propose a flocking-based framework for image structure analysis inspired by the Cucker–Smale model, interpreting pixels as interacting agents whose alignment patterns reveal self-organized regions. Here, we model each pixel as coupling with its neighbors through distance-weighted interactions, and identify structural boundaries via a normalized measure of local misalignment. This yields an edge-aware representation that suppresses intra-region variation while emphasizing transitions between self-organized flocks. We evaluate the method on diverse medical imaging data, including brain MRI, retinal fundus images, and microaneurysm patches. Across modalities, the approach robustly captures both large-scale anatomical boundaries and fine pathological details, adapting to different contrast regimes without requiring reference images. Quantitatively, strong-edge masks achieve edge/non-edge contrast ratios of ~66 in MRI, ~11 in fundus images, and ~4.4 in microaneurysm patches, with edge fractions ranging from 0.06 to 0.15—demonstrating high structural selectivity and reduced sensitivity to noise.

Abstract

Multicenter SPECT/CT radiomics is highly sensitive to variations in imaging protocols, reconstruction settings, and scanner configurations, limiting reproducibility and masking biological patterns. To address this challenge, we propose a harmonized latent radiomics framework for robust patient-level modeling in theranostic imaging. A retrospective multicenter dataset of ^{177}Lu-DOTATATE SPECT/CT scans from three institutions was analyzed. A total of 93 IBSI-compliant lesion-based radiomic features were extracted and harmonized using ComBat to reduce inter-center variability. Principal component analysis was then applied to generate a compact latent representation, followed by unsupervised clustering for lesion phenotype discovery. Patient-level representations were constructed by aggregating lesion embeddings. In addition, a perturbation strategy was implemented to assess latent-space stability and responsiveness. ComBat substantially reduced center-related variability, with η^2 values decreasing from 0.75 to near-zero levels (0.000–0.006). The latent representation demonstrated improved biological interpretability, with stronger association to intensity-related characteristics (0.351 to 0.956) and reduced dependence on texture-related confounding (0.967 to 0.528). Clustering results showed that lesion grouping was primarily driven by intrinsic phenotypic patterns rather than acquisition center. Perturbation analysis further revealed low phenotype transition rates (<10%) with gradual centroid shifts, indicating stable yet responsive latent behavior. The proposed framework combines harmonization and latent representation learning to improve robustness in multicenter radiomics and provides a promising foundation for digital twin modeling in theranostic imaging.

Abstract

Accurate dosimetry for ultra-high dose rate (FLASH) carbon ion irradiation is challenging because ionization chambers can exhibit dose rate dependent recombination and charge-collection inefficiency. Alanine/ESR dosimetry is a passive technique for high dose verification, but its response under FLASH conditions remains unclear. This study evaluated dose rate dependent alanine/ESR response by comparing calibration curves under conventional and FLASH irradiation. Alanine pellets were irradiated with a 290 MeV/u carbon ion beam at 10–100 Gy. Measurements were performed at SOBP centers under conventional irradiation at 0.09 Gy/s and FLASH irradiation at 174–265 Gy/s. An Advanced Markus chamber provided the reference absorbed dose to water. Monte Carlo simulations examined possible geometry-related dose perturbations and beam-quality effects. Under conventional irradiation, the ESR response was highly linear, and reconstructed doses agreed with the reference dose within 2%. However, applying this calibration to FLASH-irradiated alanine produced dose dependent deviations, with errors up to 28.6% in the low dose region and approximately 3–4% at higher doses. Simulations showed that chamber related scatter and positional dose differences at the alanine locations were below 1%, indicating that the discrepancy was not mainly caused by the irradiation geometry. A FLASH-specific calibration restored agreement within 1.31%, with an approximately 7.4% lower slope than the conventional calibration. These results indicate that alanine/ESR response is modified under FLASH irradiation, likely due to combined FLASH delivery and high-LET beam-quality effects. Therefore, conventional carbon ion calibration shows limited direct transferability to FLASH conditions, requiring FLASH-specific calibration for accurate dose verification.

Abstract

Accurate dose delivery in proton therapy requires reliable control of the proton range to ensure that the beam deposits its energy at the planned treatment position. However, the proton range is highly sensitive to tissue heterogeneities, anatomical changes, and patient positioning errors, making in vivo range verification an important component of proton therapy quality assurance. Positron emission tomography (PET) provides a non-invasive approach for range assessment by detecting proton-induced positron-emitting nuclei generated in the irradiated material. In this work, we demonstrate preclinical proton range verification using a dedicated in-room All-Digital PET system installed in a clinical proton treatment room. The system was evaluated using polymethyl methacrylate (PMMA) phantoms irradiated with a 130 MeV proton pencil beam. Controlled range perturbations were introduced using intact, 1 mm air-gap, and 4 mm air-gap phantom configurations. PET data were acquired for 300 s following irradiation, and one-dimensional activity profiles were extracted. At 130 MeV, the PET-derived activity profiles exhibited distinct distal fall-off shifts that correlated with the introduced air gaps. These results demonstrate the capability of the system to resolve millimeter-scale range perturbations under the tested phantom conditions and provide experimental support for future preclinical animal studies and clinical in-room proton therapy verification.

Abstract

Proton therapy is recommended as the "new standard-of-care option for patients with head and neck oropharyngeal cancer". Still, the absence of a monitoring tool equivalent to electronic portal imaging hinders its upmost potential, and forces the application of safety margins and field-patching, thereby increasing the dose to normal tissue. Prompt gamma-rays produced along the proton track can cover this shortfall, since their production cross section is strongly correlated with the proton dose depth profile. We present the first experimental proof of principle of proton range verification with a single-channel prompt gamma-ray detector located behind the treated area, in coaxial geometry. Simple heterogeneous targets were irradiated with 1e8 protons at clinically realistic energies at beam currents of 1.6 nA. The mean statistical precision was 1 mm (sigma). The absolute experimental error with respect to the ground truth predicted by a Monte Carlo simulation was 2 mm on average. These findings encourage further investigations with anthropomorphic phantoms and realistic treatment plans, and could open up the door for proton range verification with a single scintillation detector, that may have better prospects of integration into rotating gantries and compact treatment rooms than collimated multi-channel systems.

Abstract

Positron emission tomography (PET) has been widely investigated for range verification in carbon-ion radiotherapy (CIRT). All-Digital PET, based on multi-voltage threshold (MVT) direct digital signal acquisition with high count-rate capability, represents a promising new approach for in-beam monitoring. However, its application in CIRT remains largely unexplored, and experimental validation under realistic irradiation conditions is still lacking. In this study, we report the preliminary experimental validation of an in-beam All-Digital PET system for range verification in CIRT. A discrete 7x7 raster-scanned carbon-ion field (261.03 MeV/u) with a spot spacing of 5 mm and a delivery of 2000 MU per spot was delivered to a polymethyl methacrylate (PMMA) phantom (6x6x15 cm³). To simulate localized anatomical heterogeneity, a cylindrical air cavity with a diameter of 1 cm was embedded at a depth of 5 cm from the beam entrance, introducing an approximate local range shift of 10 mm. Two-dimensional distal range maps successfully revealed the irradiation field and clearly identified the cavity boundary. Within the region of interest, the measured localized range shift was 9.14 mm, with a residual error of only 0.86 mm compared with the ground truth. These results demonstrate the feasibility of All-Digital PET for accurate in-beam range verification under clinically relevant raster-scanned carbon-ion delivery conditions and support its potential for future CIRT applications.

Abstract

Targeted radionuclide therapy employs therapeutic radiation-producing radionuclides bound to targeting agents to selectively damage cancer cells. Recent interest has expanded beyond conventional beta emitters to include alpha emitters and Auger electron emitters. We investigated the therapeutic potential of the ^{134}Ce/^{134}La pair by comparing its DNA damage induction with commonly used radionuclides. A simplified human fibroblast cell model was implemented using Monte Carlo track-structure simulations to evaluate single-strand and double-strand DNA break yields. Particular attention was paid to the various spatial distributions of the radiation source. In this simulation, radionuclides were distributed at the cell surface, cytoplasm, and nucleus surface; both physical and chemical stages of radiation interaction were modeled, including indirect damage mediated by hydroxyl radicals. The results show that double-strand break yields increase as radionuclide localization approaches the nucleus, while single-strand break yields remain relatively stable. Indirect effects dominate DNA damage formation across all radionuclides and spatial distributions. The ^{134}Ce/^{134}La pair demonstrates DNA damage yields comparable to established beta and Auger electron emitters under all tested conditions. Although these findings do not directly translate to therapeutic efficacy, they indicate that this radionuclide pair has competitive radiobiological effectiveness and warrants further investigation for potential application in targeted radionuclide therapy.

Abstract

Particle therapy with protons and carbon ions offers conformal dose delivery, but its clinical benefit strongly depends on accurate verification of the beam range inside the patient. The TIARA (Time-of-Flight Imaging ARray) detector has been developed to address this challenge through the exclusive measurement of Prompt-Gamma (PG) Time-of-Flight (TOF). The system combines a fast plastic beam monitor with arrays of Cherenkov gamma detectors based on PbF_2 crystals coupled to SiPMs, enabling sub-nanosecond timing performance and real-time treatment verification.

An 8-channel prototype has been tested with proton and carbon-ion beams delivered by cyclotrons, synchro-cyclotrons and synchrotrons. Measurements with 63 MeV protons at the MEDICYC cyclotron demonstrated a range accuracy of 3.3 ± 0.1 mm (2σ) for irradiation spots of about 2×10^7 protons, corresponding to roughly 3200 detected PG events. Experiments with carbon ions at the CNAO synchrotron achieved a range accuracy of 4.74 ± 0.36 mm (2σ) at clinical intensity by grouping four spots of 2.4×10^6 ions each, with approximately 5600 detected PGs. These results confirm the high sensitivity of the TOF approach for proton and carbon-ion therapy.

Beyond range monitoring, TIARA implements the Prompt Gamma Time Imaging (PGTI) method to identify anatomical changes occurring between treatment planning and dose delivery. An iterative reconstruction algorithm was developed to merge the TOF information from multiple detector modules and reconstruct both the PG emission profile and the proton beam average velocity evolution inside the patient. The method was validated using a RANDO head phantom irradiated at the Proteus One accelerator under two anatomical configurations simulating an empty and filled sinus cavity. The reconstructed PG distributions enabled localisation of the induced anatomical change, demonstrating the potential of TIARA for adaptive particle therapy and in vivo tissue identification.

Abstract

Accurate in-vivo range verification is essential for realizing the full dosimetric advantage of carbon-ion therapy [1]. Secondary electron bremsstrahlung (SEB), a low-energy photon emission produced along the beam trajectory inside the patient, has attracted attention as a prompt signal for non-invasive range monitoring [2]. While our prior work demonstrated the principle using a pinhole collimator, the limited collection efficiency of a pinhole aperture imposes a fundamental constraint on range estimation precision [3]. A knife-edge slit geometry offers a one-dimensional focusing advantage that substantially raises the collected photon flux compared to the pinhole-based approach. In this study, a knife-edge slit camera equipped with a Ce:GAGG scintillator array was constructed and evaluated through irradiation experiments with a 290 MeV/u carbon-ion beam at the Heavy Ion Medical Accelerator in Chiba (HIMAC). The camera employed a tungsten knife-edge slit collimator with a slit width of 1 mm and a thickness of 48 mm, positioned 490 mm from the beam axis with a collimator-to-detector distance of 49 mm. The Ce:GAGG scintillator array consisted of 1.5 × 1.5 × 1 mm³ crystals arranged in a 16 × 16 matrix with a pitch of 1.6 mm. One-dimensional SEB profiles were measured over a range of beam range conditions by varying the range-shifter thickness, and representative results are presented. The acquired distributions exhibited a systematic dependence on beam range, with a 5 mm increment reliably distinguished by visual inspection. Quantitative range estimation yielded an uncertainty of 2.89 mm for 10^8 ions; further details will be presented at the conference.

Abstract

Proton therapy requires accurate in *vivo* dose verification because proton range uncertainties may compromise treatment precision. This study aimed to develop and evaluate a deep learning-based method for three-dimensional (3D) dose reconstruction using positron emission tomography (PET) in proton therapy.

A dual-panel PET system with time-of-flight and depth-of-interaction (TOF-DOI) capability was modeled using GATE Monte Carlo simulations. PET activity images and corresponding ground-truth dose maps were generated for single pencil beams with energies across 60–120 MeV. A U-Net-based neural network was developed to reconstruct the 3D dose distributions from reconstructed PET activity images. Quantitative evaluation was performed using 3D gamma passing rates (GPRs) and distal range metrics (R_{50} and R_{90}).

The proposed method accurately reconstructed 3D dose distributions while reduced the impact of limited-angle artifacts inherent to the dual-panel PET geometry. GPRs exceeded 99% under the 3%/3 mm criterion and 98% under the 2%/2 mm criterion for all validation datasets. Submillimeter accuracy was achieved for distal range verification, with maximum deviations of 0.15 mm for R_{50} and 0.11 mm for R_{90}.

The results demonstrate the feasibility of using a dual-panel PET system with a deep learning method for accurate 3D dose reconstruction and proton range verification, supporting its potential in proton therapy quality assurance.

Abstract

In-beam PET is a promising technique for range verification in particle therapy because positron emitters are produced along the beam path through nuclear fragmentation reactions. Over the past years, QST has developed a human-scale OpenPET system that enables three-dimensional PET imaging during and/or immediately after carbon-ion therapy. In parallel, LMU has developed an analytical approach based on a pencil beam algorithm for irradiation-plan-based PET image prediction. In the present study, we combine these two developments toward the clinical implementation of OpenPET for range verification in carbon ion therapy. The approach involves comparing measured OpenPET images with predicted PET images.

Phantom experiments were performed at HIMAC. OpenPET data were acquired during and after irradiation. To simplify PET image prediction, the present analysis was limited to the post-irradiation period, and list-mode data acquired from 0 to 600 s after the end of irradiation were extracted and reconstructed as the measured OpenPET image. A predicted PET image corresponding to the same 0-600 s post-irradiation period was generated from the irradiation plan and PET measurement conditions by modeling positron-emitter production and physical decay.

The predicted PET images showed an activity distribution corresponding to the planned irradiation fields, and the comparison indicated reasonable agreement between the predicted and measured images. These results demonstrate the feasibility of combining OpenPET with the irradiation-plan-based PET prediction, and they support the potential of the clinical use of OpenPET for range verification in carbon-ion therapy.

Abstract

Accurate quality assurance (QA) is essential in proton therapy, where the steep dose gradient of the Bragg peak requires precise knowledge of beam position to spare healthy tissue while ensuring full tumor coverage. This work presents the experimental evaluation of easyPET.3D, a compact and cost-effective preclinical PET scanner, as a potential tool for pretreatment QA in proton therapy using phantoms.Homogeneous PMMA phantoms were irradiated at the Paul Scherrer Institute (PSI) Gantry 1 facility with proton energies ranging from 138 to 195 MeV, delivering up to 6.4 × 10^{11} protons per irradiation. The resulting 3D β+ activity distributions were reconstructed and analyzed to characterize both longitudinal range and transverse beam profiles. A temporal convergence study determined the minimum acquisition time required for stable range estimation. In addition, a controlled displacement experiment, with longitudinal offsets of 1, 2, 3, and 5 mm, was performed to assess the system's ability to detect range variations.Transverse analysis revealed energy-dependent beam broadening, with mean FWHM values decreasing from 12.3 mm at 138 MeV to 9.6 mm at 195 MeV, and a characteristic widening near the distal end consistent with proton stopping at the Bragg peak. Range estimation converged within 10–12 cumulative frames (~30–35 min). Sensitivity tests showed that the system could detect longitudinal phantom displacements as small as 1 mm, with a linear response and a systematic overestimation of 13%, attributed to manual positioning uncertainties.These results demonstrate that easyPET.3D is a promising and accessible solution for pretreatment QA in proton therapy workflows.

Abstract

Multi-time-point SPECT/CT is used for patient-specific dosimetry after Lu-177-PSMA therapy. However, inter-scan motion, anatomical deformation, and time-dependent uptake variations can compromise volume-of-interest (VOI) activity extraction and time-integrated activity (TIA) estimation, thereby requiring accurate inter-time-point SPECT registration. This study proposes a structure-weighted CT-guided registration method for longitudinal SPECT/CT. Organ-specific dosimetric priorities and an uptake-derived activity-concentration term were integrated into a spatial weight map, which was incorporated into the CT registration similarity metric to emphasize structures with greater dosimetric relevance. The resulting CT-derived transformation was applied to SPECT images using physical-coordinate inverse mapping. Compared with Elastix and an unweighted baseline, the proposed method improved SPECT VOI Dice similarity coefficient (DSC) from 0.82 with Elastix and 0.87 with the unweighted baseline to 0.90. It also reduced fitting-residual-based TIA normalized root-mean-square error (nRMSE) across all evaluated structures, with additional reductions relative to the unweighted baseline of 15.8% in kidneys, 23.2% in prostate, and 49.2% in tumors. These results indicate that incorporating dosimetric structure weighting into CT-guided registration can improve dosimetry-relevant spatial consistency and temporal fitting stability in multi-time-point SPECT/CT workflows for radionuclide therapy.

Abstract

Boron Neutron Capture Therapy (BNCT) is a binary radiation treatment relying on the selective uptake of B-10 in tumors, requiring a high thermal neutron flux with minimal fast neutron and gamma ray contamination. The reaction between the thermal neutron and the B-10 releases an alpha and lithium nucleus, two high-LET particles that deposit their energy inside the cell causing lethal damage. This work characterizes a BNCT-optimized irradiation field at a TRIGA Mark II reactor and compares the effects on various cell samples to standard radiation fields. The irradiation setup was localized within the graphite thermal column of the TRIGA reactor (Mainz). Gamma contamination was mitigated using lead shielding, while additional graphite bars further thermalized the neutrons. Dosimetric profiling was conducted using radiochromic films paired with specific radiation converters. Additionally, PADC plates were employed to quantify the alpha particle tracks emitted by the BNCT reaction, as well as proton tracks generated by the elastic scattering of fast neutrons. For biological validation, FaDu tumor cells and isolated lymphocytes were exposed to nominal doses (1–6 Gy) to evaluate clonogenic survival and DNA double-strand breaks (DSB) via the γH2AX foci assay. Experimental data were cross-referenced with Monte Carlo (GATE/Geant4) cellular microdosimetric models. Dose contributions from primary beam components were assessed across different shielding configurations to optimize the thermal neutron field, and microdosimetric models were applied to estimate biological sample doses. Results demonstrated linear dose-response relationships for lymphocyte DNA damage, while tumor cell survival was reduced compared to photon reference data, due to relative biological effectiveness of thermal neutrons.

Ultimately, this integrated experimental and computational methodology validates the reactor facility for advanced BNCT research.

Abstract

Compton cameras are a potential tool for assessing translational targeted alpha therapy (TAT) treatments using ^{225}Ac in murine models. For this application, gamma cameras perform sub-optimally due to the extremely low activities used. The IRIS group at IFIC-Valencia is developing Compton cameras based on lanthanum bromide ($LaBr_3$) crystals, capable of visualizing ^{225}Ac distributions through the detection of the 440 keV gammas emitted during the decay of its short-lived daughter nuclide ^{213}Bi. Following successful imaging tests with ^{131}I in live mice at CIC biomaGUNE in San Sebastián, Spain, this work presents measurements performed using the current Compton camera prototype, MACACO III+, and a mouse phantom filled with ^{225}Ac. The system was shown to be capable of visualizing ^{225}Ac distributions in the phantom with two combinations of organ compartments filled with activity. Images obtained using the Compton camera are of comparable quality to those obtained using commercial pre-clinical SPECT systems at 440 keV. Monte Carlo simulations of a mouse phantom filled with ^{225}Ac have also demonstrated the improved image quality that can be achieved with an augmented Compton camera, MACACO IV, featuring a larger first plane detector and currently under development. Measurements using MACACO III+ for imaging live mice grafted with AR42J tumor cells and injected with [^{225}Ac]Ac-DOTATATE are planned for the near future.

Abstract

Boron Neutron Capture Therapy is a binary cancer treatment modality in which a tumour-selective boron-carrying drug is administered to the patient prior to irradiation with a neutron beam. The highly localised nuclear reaction between thermal neutrons and ^{10}B deposits a lethal radiation dose selectively within tumor cells. After recent advances driven by accelerator-based neutron sources and improved boron compounds, a critical gap remains: there is currently no method to image boron distribution in vivo during treatment, preventing real-time dose verification.

We present the development of a Compton camera system designed to detect the 478 keV prompt gamma rays emitted following ^{10}B neutron capture, thereby enabling direct spatial mapping of boron dose deposition. The detector is based on $LaCl_3$ and $CeBr_3$ scintillators arranged in a pyramidal geometry, inherited from nuclear physics instrumentation developed at CERN-n_TOF, which provides intrinsically low neutron sensitivity and high gamma-ray detection efficiency.

Experimental validation was carried out at Institut Laue-Langevin (ILL, Grenoble). A boron sample in water at 65 ppm, within the clinically relevant concentration range, was successfully imaged, yielding a signal-to-background ratio of 12. This constitutes, to our knowledge, the first experimental demonstration of Compton imaging of boron at clinical concentration levels.

At treatment-level neutron fluxes, however, the original detector suffered from count rate saturation. To address this, we redesigned the detector incorporating pixelated crystal arrays. The pixelated prototype was subsequently validated at the LENA reactor (U. Pavia) achieving a reduction in per-crystal count rate by a factor of approximately 250.

These results represent a substantive step toward a clinically deployable real-time boron imaging system, with implications both for treatment monitoring of patients and preclinical pharmacokinetic studies with animal models.

Abstract

Proton therapy enables conformal tumor irradiation while reducing dose to surrounding healthy tissues. But anatomy, motion, and delivery uncertainty can cause differences between planned and delivered dose. PET can detect proton-induced positron-emitting radionuclides such as ^{15}O, ^{13}N, & ^{11}C, providing a method for post-irradiation in-vivo dosimetry verification. We evaluated a mobile PoC-PET system for imaging validation & MLEM-based radionuclide decomposition.

PoC-PET used 8 TOF detector modules. Imaging performance was evaluated with a Derenzo-style tumor phantom 3.3-11.4mm lesions at a 20:1 tumor:background ratio and with a FDG-injected mouse. To evaluate radionuclide decomposition, three vials with known ^{15}O, ^{13}N, & ^{11}C activities were imaged for 60 minutes. Counts were binned in 30s windows and reconstructed into PET image series. ROIs generated decay curves modeled as mixtures of exponential decay components using an MLEM-based fitting approach.

PoC-PET resolved all tumor clusters by the VPR < 0.735 criterion. Mouse imaging clearly showed regional FDG uptake with spatial agreement to MicroPET. In the multi-isotope experiment, the MLEM fit matched the large-ROI decay curve with a ~1% nRMSE. The fitted isotope allocation captured expected isotope behavior: ^{15}O dominating early, ^{13}N showing intermediate decay, and ^{11}C persisting throughout the scan. The injected mixture was 29% ^{11}C, 16% ^{13}N, and 55% ^{15}O, the MLEM estimated 27.7%, 15.7% and 56.6% respectively.

These results demonstrate the feasibility of using a mobile PoC-PET system and radionuclide decomposition for post-irradiation radionuclide characterization.

Abstract

Multi-time-point SPECT/CT imaging enables improved characterization of radiotracer kinetics for quantitative dosimetry, particularly in emerging radiopharmaceutical therapies. However, activity quantification is affected by partial volume effects (PVE), which introduce time-dependent bias in both lesion and organ dose estimation. This issue is especially relevant for novel radionuclides such as ^{161}Tb, where complex emission characteristics may lead to varying sensitivity to image correction across time. In this study, we analyze the temporal behavior of lesion and organ dosimetry for ^{161}Tb-FAPI-2286 and evaluate the influence of partial volume correction at multiple imaging time points (2 h, 24 h, and 96 h post-injection). Patient-specific SPECT/CT data were used, with lesions and organs segmented using semi-automatic and deep learning-based approaches. Two iterative correction methods, Richardson–Lucy and reblurred Van Cittert (RVC), were applied prior to dosimetric analysis. Absorbed dose values were estimated using Monte Carlo simulations, and relative differences were computed between corrected and non-corrected images. Results indicate minimal impact of correction at early imaging, with relative differences generally below ±3%. In contrast, substantial and heterogeneous variations were observed at later time points, with lesion-level dose changes ranging from approximately −30% to +38%. Bone lesions exhibited the largest positive deviations, whereas lung lesions showed consistent reductions at delayed imaging. Both correction methods demonstrated similar temporal patterns, with slightly lower variability for the RVC approach. These findings highlight the time-dependent nature of PVE in ^{161}Tb-based dosimetry and emphasize the importance of incorporating correction methods in delayed imaging. Temporal-aware quantitative strategies are therefore essential for improving the reliability of lesion-level dose estimation in emerging theranostic applications.

Abstract

The development of integrated strategies for simultaneous cancer detection and treatment is driving advanced theranostic platforms. In this context, the COXIRIS system (Confocal Orthovoltage X-Ray Induced Radiation Integral System) introduces a large-scale X-ray fluorescence (XRF) imaging architecture designed to combine real-time functional imaging with precision-guided therapy.This work evaluates the feasibility of COXIRIS for imaging and guiding treatment of tumors labeled with high-Z biomarkers or nanoparticles (e.g., Au, Gd). The system uses XRF detection with a collimated X-ray source directed toward a focal inspection region, while a synchronized high-sensitivity detection system performs three-dimensional scanning and tumor localization. The partially confocal detection geometry improves spatial selectivity at macroscopic scale and enables guidance of therapeutic modalities including radiotherapy, ablation, drug delivery, and surgical assistance.Experimental results demonstrated tumor localization at depths up to 15 cm in tissue-equivalent media using low radiation dose levels. Gadolinium-based targets were detected in less than 2 seconds at this depth. Although acquisition times are currently comparable to some nuclear medicine procedures, scalability through larger detector areas and optimized geometry indicates potential for sub-second detection.COXIRIS represents a novel large-scale XRF imaging and theranostic guidance platform that addresses limitations of existing micro-scale XRF techniques. Its compatibility with conventional radiotherapy systems, including linear accelerators and orthovoltage units, supports its translational potential for real-time and personalized cancer treatment.

Attenuation Correction Using 176Lu Background in Limited-Angle Flat-Panel Total-Body PET (#1490)

Thibault D'Hulster, Jens Maebe, Stefaan Vandenberghe

Ghent University, MEDISIP, Ghent, Belgium

Abstract

A novel flat-panel total-body walk-through PET system under development at Ghent University aims to improve patient throughput and cost-effectiveness compared to conventional total-body scanners. Its high sensitivity enables low-dose imaging protocols, where CT may be omitted to minimize radiation exposure. In this setting, an alternative CT-less attenuation correction method is required. The high sensitivity and large number of LYSO detector elements in the walk-through geometry also result in a substantial and potentially exploitable intrinsic background signal from ^{176}Lu.

This GATE simulation study investigates the feasibility of leveraging this intrinsic ^{176}Lu background activity in the LYSO detectors for transmission-based attenuation estimation. The limited angular coverage inherent to the flat-panel design introduces additional challenges for implementation of this method. To address this, a maximum likelihood transmission reconstruction (MLTR) algorithm was implemented. MLTR is particularly interesting for low-dose applications because it is independent of emission data and computationally efficient, making it suitable for clinical integration.

The effect of limited-angle artifacts on attenuation map convergence was evaluated, along with their impact on attenuation correction in PET image reconstruction, using a full angular coverage flat-panel geometry with side panels as reference. Simulations with a NEMA image quality phantom and the XCAT phantom demonstrated that limited angular coverage has minimal impact on attenuation correction in emission image reconstruction. These transmission-based attenuation maps may further serve as initial estimates for more advanced approaches, such as maximum likelihood reconstruction of attenuation and activity (MLAA) or physics-informed deep learning methods.

Abstract

A DOI-enabled total-body TOF PET system with a 200-cm axial field of view was developed using 2-mm-pitch LYSO crystal arrays and light-sharing-window-based DOI encoding. The system consists of seven detector rings with a transaxial diameter of 70 cm. Phantom experiments, including SZBL logo, Derenzo, and dynamic line-source phantoms, were performed to evaluate imaging performance. The reconstructed logo phantom demonstrated clear visualization of 2-mm structures, while rods down to 2.0 mm could be distinguished in the Derenzo phantom, indicating high spatial resolution consistent with the detector crystal pitch. Dynamic imaging results demonstrated continuous tracer propagation across consecutive 5-s frames, indicating high sensitivity and short-frame dynamic imaging capability. In addition, TOF resolution measurements based on the NEMA NU 2-2018 method achieved approximately 330 ps for both single-ring and dual-ring configurations. These results demonstrate the feasibility of integrating DOI capability, high spatial resolution, dynamic imaging capability, and stable TOF performance within a long axial field-of-view total-body PET system.

Abstract

Total-Body Positron Emission Tomography systems offer substantially increased sensitivity due to their extended axial FOV, enabling reduced dose, shorter acquisitions, or improved image quality. Incorporating TOF information further enhances image reconstruction by improving Signal-to-Noise Ratio. We have recently developed and installed a novel TB-PET scanner (IMAS) at Hospital La Fe in Valencia (Spain). The system is based on semi-monolithic LYSO crystals and provides TOF and Depth of Interaction (DOI) capabilities. In this work, we present the implementation and evaluation of TOF and scatter correction for the IMAS system, and we also present ongoing developments related to random, dead time, and quantification corrections are presented.

For the TOF information, an iterative skew correction was used. Scatter correction was applied using a TOF-based scaling method. For the random, dead-time and quantification correction study, the acquisition mode was modified allowing the acquisition of coincidences and singles at the same time.

A system CTR of 690 ps was measured at the NECR peak. The combined use of TOF and DOI information and the inclusion of scatter correction demonstrated a reduction in positional errors for off-center lesions and an improvement of the SNR, contributing to improving the image quality of the IMAS system.

Addressing Scatter Phantom Length Limitations: A Single-Scan Multi-Position Method for NEMA NU 2 Testing of Long Axial FOV PET Systems (#2290)

Hancong Xu, Yifan Wu, Yilin Liu, Liuchun He, Yun Dong

United-imaging Healthcare Co., Ltd., MI-RECON, Shanghai, China

Abstract

The NEMA NU 2 scatter phantom (70 cm, ~20 kg) was designed for conventional PET scanners with axial fields-of-view (AFOV) under 30 cm. For long axial field-of-view (LAFOV) systems exceeding 70 cm, this phantom provides only a localized assessment that fails to capture out-of-FOV scatter and randoms from the full body. Scaling the phantom to 1.2–1.75 m would increase its weight to 34–50 kg, rendering routine use impractical. We propose a single-scan multi-position protocol that exploits the idle intervals between static acquisitions in a standard decay experiment to reposition the phantom axially within each time slot. A center-plus-off-center demonstration was performed on a uMI Panorama GS (1.5 m AFOV). The 70-cm phantom was measured at both the AFOV center and 10 cm beyond the AFOV edge, with the off-center position sampled twice per slot to enable interpolation to a common activity level. The two off-center acquisitions showed close agreement across all count rate metrics and scatter fraction (SF), confirming reproducibility. The SF at the off-center position was elevated due to out-of-FOV scatter contributions, consistent with total-body imaging conditions. This approach enables evaluation of LAFOV systems at multiple axial positions without additional phantom preparation, offering a practical basis for NEMA NU 2 evalution metrics related to the scatter phantom experiment.

Abstract

Lung cancer (LC) is increasingly recognized as a systemic disease, with metabolic alterations that may vary across histological subtypes. Smoking is a major LC risk factor, but its effects on systemic metabolism and tumor phenotypes across LC subtypes remain insufficiently characterized. We integrated systemic metabolic networks and tumor habitat imaging from static and dynamic total-body ^{18}F-FDG PET/CT to characterize smoking effects across LC subtypes. This multicenter study included 125 LC patients and 200 healthy controls from three centers. Thirty-seven regions spanning the central nervous system and peripheral organs were analyzed. Regional SUL_{mean} values and time–activity curves were harmonized using ComBat and adjusted for demographic covariates. Population-level metabolic networks were constructed from bootstrapped Pearson correlations of regional uptake, while individual-level networks were derived from residual time-activity curve correlations after third-order polynomial fitting to calculate organ-specific abnormality strength. Tumor habitats were defined using PET/CT intensity and entropy features, and their associations with smoking and organ abnormalities were assessed by multivariable regression and mediation analyses. Both network analyses showed that smoking disrupted systemic metabolic coordination in a subtype-dependent manner, with the liver emerging as a central hub. Tumor habitat imaging revealed a smoking-associated shift toward hypometabolic tumor microenvironments. Mediation analysis suggested that habitat composition modulated the association between smoking and hepatic metabolism, linking local tumor heterogeneity to systemic metabolic responses. These findings demonstrate that integrated metabolic network and tumor habitat imaging from total-body ^{18}F-FDG PET/CT provides quantitative insight into smoking-related systemic metabolic reprogramming in LC and may support imaging-based characterization across histological subtypes.

Abstract

Deep learning models for PET image enhancement often struggle to generalize across unseen scanner configurations due to limited training data diversity. We introduce a Domain Randomization (DR) framework that utilizes Monte Carlo simulations via the SimPET platform to randomize scanner geometries and reconstruction protocols within clinically operational ranges. To mimic biological variability, this approach is supplemented by a tailored activity augmentation pipeline, resulting in a training dataset of 232 activity maps. To validate this methodology, we trained a 2.5D Attention U-Net to map simulations to high-quality activity maps. Performance was assessed across incremental data regimes ranging from 20 to 236 training instances. On unseen scanner domains, the DR strategy consistently outperformed the no-DR baseline in SSIM and relative contrast. Conversely, on the in-distribution source domain, the DR model achieved perceptual equivalence to the baseline, despite a minor trade-off in absolute pixel precision. Real-world validation with a Hoffman Phantom acquisition on a Philips Vereos scanner suggested a remaining sim-to-real gap on real data distributions. By demonstrating improved generalization without compromising structural fidelity on synthetic domains, this work presents a promising pathway for future research and democratizes access to high-quality, annotated training data through scalable and cost-effective deep learning tools.

Abstract

Spatiotemporal Emission Reconstruction from Prompt Gamma Timing data (SER-PGT) has the potential to verify the stopping power through passive measurements during proton therapy. The underlying inverse problem is ill-posed and offers some unusual challenges compared to conventional emission or transmission reconstruction scenarios.In this work, we introduce an unsupervised deep learning framework for reconstructing prompt gamma emission distributions from simulated data, without requiring ground-truth images during training. Our method combines a physics-informed Poisson likelihood loss in the data domain with a UNet++ architecture with ResNeXt101 encoder. It operates on pseudo-inverse reconstructions from a system matrix modeling 110 detectors, 160 depth bins, and 100 time bins. Evaluation on 200 test samples yields comparable performance to MLEM in terms of Mean Absolute Error and Peak-Signal-to-Noise-Ratio in both image and data domains, demonstrating that accurate reconstruction is achievable through self-supervised learning. The approach showcases fast execution speed and a flexible framework. This makes it a promising candidate to move SER-PGT closer towards stopping power estimation in clinical scenarios.

Abstract

This study investigates the cross-site generalization of deep learning for Tc-99m ethyl cysteinate dimer (ECD) brain perfusion single-photon emission computed tomography (SPECT), where site-specific imaging variability often limits cross-site generalization of deep learning models. To address this, a multi-site supervised contrastive learning (SupCon) pretraining framework was developed using a 3D ResNet-18 encoder, which was trained on 2,242 images collected from five sites across eight diagnostic categories. The pretrained representation achieved a latent-space silhouette score of 0.815, while t-SNE visualization showed that samples from different sites were well mixed within diagnostic clusters, indicating that the learned features were more disease-discriminative than site-specific. To simulate deployment at a new hospital, a sixth site that had been entirely excluded from pretraining was reserved for downstream evaluation. In this hospital-held-out setting, where only 46 balanced samples were available for adaptation, few-shot fine-tuning achieved 80.4% accuracy for Alzheimer's disease-versus-Normal classification, with a macro F1-score of 0.801 and an area under the receiver operating characteristic curve (AUC) of 0.819. This performance substantially exceeded that of a randomly initialized baseline, which achieved 60.9% accuracy, a macro F1-score of 0.568, and an AUC of 0.639. These results suggest that multi-site SupCon pretraining may provide a practical route toward scalable cross-site deployment of brain SPECT classifiers with minimal site-specific annotation, potentially enabling rapid clinical adoption at new hospitals.

Large Language Models for Generating Descriptions of 3D Medical Image Volumes (#1604)

Joshua Schaefferkoetter, Paul Schleyer

Siemens Medical Solutions USA, Inc., Knoxville, USA

Abstract

This paper presents an approach for using large language models to automatically generate descriptions for 3d medical images. It describes a novel method for encoding volumetric data into a discrete set of tokens, which are then used to condition the text generated by a pre-trained foundational language model. Design considerations and model architecture are outlined, and the feasibility of the technique is demonstrated for generating descriptive captions of image volumes with information related to imaging modality, administered radiopharmaceutical and anatomical scan range.

Abstract

Synthetic computed tomography (sCT) generation from magnetic resonance imaging (MRI) is an important component of MRI-only radiotherapy planning because MRI provides excellent soft-tissue contrast but lacks quantitative Hounsfield unit (HU) information for electron-density assignment. However, MRI-to-sCT synthesis remains challenging due to the indirect MRI representation of bone, the ambiguity between intra-body air and external background, and the heterogeneous HU distributions across anatomical regions. This study proposes a region-aware 3D supervised MRI-to-sCT synthesis framework using paired CT-referenced MRI and CT volumes. The network combines 3D convolutional feature extraction with a Project-and-Excite (PE) attention module to enhance volumetric anatomical representation. To improve HU fidelity in clinically relevant regions, MRI masks were used for input background suppression, CT body masks were used to define valid supervision and evaluation regions, and HU-derived masks were used to impose region-weighted constraints on body, background, intra-body air, and bone regions. The method was evaluated on 24 paired MRI/CT cases, including 16 training, 5 validation, and 3 independent testing cases. In ablation analysis, the full body–background–air–bone loss achieved the highest PSNR of 19.65 dB, while SSIM decreased to 0.53, suggesting improved control of large HU deviations rather than simple maximization of structural similarity. These preliminary results support the feasibility of region-aware HU optimization for MRI-to-sCT synthesis, while larger-scale validation, region-wise HU analysis, and dosimetric assessment remain necessary before clinical application.

Abstract

Tau positron emission tomography (PET) is strongly linked to cognitive impairment and disease progression in Alzheimer's disease, but direct tau imaging is not always available in routine clinical or research workflows. This study evaluated a multimodal deep learning framework that uses amyloid PET and fluorodeoxyglucose (FDG) PET to estimate binary ^{18}F-flortaucipir (FTP) positive/negative status. A total of 340 participants from Alzheimer's Disease Neuroimaging Initiative (ADNI) and the Geneva University Hospital cohort with available amyloid, FDG, and FTP PET were included. Images were registered to Montreal Neurological Institute space and used as two-channel volumetric input to a SwinUnetR-based classifier. The multimodal model setting was evaluated using stratified five-fold cross-validation on the combined cohort. The model achieved an accuracy of 0.853, sensitivity of 0.823, specificity of 0.871, and area under the receiver operating characteristic curve of 0.904. These findings suggest that combined amyloid and FDG PET contains complementary information relevant to tau status and may provide practical decision-support evidence when direct tau PET is unavailable or when the indication for tau imaging remains uncertain.

Work supported by German Research Foundation.

Abstract

In this work, a physics-aware neural network architecture is proposed for Compton camera image reconstruction. The model incorporates physics-based features from coincidence events and uses backprojection as a prior. It is applied both to mono energetic sources as well as to targeted alpha therapy using Actinium-225 where the presence of multiple gamma-ray lines makes image reconstruction more challenging for existing medical imaging devices, such as single-photon emission computed tomography. The input data are preprocessed and categorized into scattering-only, absorption-only, and coincidence events. These data are used to generate feature maps through neural network layers and a transformer-based model, followed by an image reconstruction decoder. Training and testing data were generated using the Geant4 simulation toolkit. The model was first evaluated using controlled single-source simulations with different source sizes, energies, positions, and event statistics. It was then tested under more realistic conditions using a mouse phantom with Actinium-225 activity distributed in tumor and background regions. CPPF-Net achieved a mean peak-localization error of 1.0 ± 0.7 mm and a structural similarity index of 0.99 ± 0.01. These results indicate that CPPF-Net can provide accurate Compton camera image reconstruction for Actinium-225 targeted alpha therapy. Experimental validation with measured data is foreseen for the near future.

Abstract

Prostate cancer is one of the most commonly diagnosed cancers in men worldwide. Accurate detection using ^{18}F-prostate-specific membrane antigen (PSMA) positron emission tomography/computed tomography (PET/CT) enables reliable identification of the disease and supports clinical staging. In this study, we propose a deep learning framework for the slice-level classification of ^{18}F-PSMA PET/CT images using convolutional neural networks trained on axial, coronal, and sagittal views. The models achieved high discrimination performance, with an area under the receiver operating characteristic curve of 0.98 and a specificity of 0.98, while showing orientation-dependent differences in sensitivity and classification balance. However, lower performance in the hold-out dataset indicates limited generalization capability, highlighting the importance of imaging plane selection in prostate tumor classification. The classification model serves as a preliminary step for downstream segmentation by enabling slice-level localization of the region of interest.

Equilibrium Matching for PET Image Denoising: Signal vs. Velocity Parameterization Under Identical Conditions (#2453)

Shaghayegh Afshari, Cheng-Ying Chou

National Taiwan University, Department of Biomechatronics Engineering, Taipei, Taiwan

The authors declare no external funding for this work.

Abstract

Low-count Positron Emission Tomography (PET) suffers from severe Poisson photon-counting noise, yet existing deep learning denoisers either rely on supervised regression networks that tend to oversmooth anatomical detail or on diffusion-based generative models designed for Gaussian corruption that require iterative, noise-level-dependent sampling at inference time. Equilibrium Matching (EqM) was recently proposed as a generative modeling framework that learns a time-invariant equilibrium gradient field toward the data manifold, but has not yet been explored for medical image restoration. We present a novel adaptation of EqM to PET denoising, reformulating its interpolation scheme for Poisson-corrupted acquisitions and introducing noise-level conditioning via Adaptive Group Normalization, and conduct a controlled comparison of its two parameterizations under identical training conditions: the signal form, which predicts the clean image directly with hyperparameter-free inference, and the velocity form, which predicts the noise residual via iterative Euler updates. Signal EqM achieves up to +5.26 dB PSNR gain at severe noise (N_peak = 50) with no step-size tuning. Velocity EqM consistently outperforms signal EqM on both PSNR and FID at all seven noise levels, with the PSNR gap growing from 0.13 dB at N_peak = 50 to 1.23 dB at N_peak = 5000, mirroring the x- vs. velocity-prediction trade-off in flow-based generative models.

CT-VDETR: Semi-supervised 3D Trauma Detection in Computed Tomography (CT) scans using Dense Vertex Relative Position Encoding (#2592)

Shivam Chaudhary, Sheethal Bhat, Andreas Maier

Friedrich-Alexander-Universität Erlangen-Nürnberg, Pattern Recognition Lab, Erlangen, Germany

We sincerely acknowledge the Erlangen National High Performance Computing Center (NHR@FAU) of the Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU) for providing the necessary computing resources that enabled this research.

Abstract

Accurate detection and localization of traumatic injuries in abdominal CT remain challenging because voxel-level annotations are limited and expensive to obtain. We present a label-efficient framework for 3D abdominal trauma detection that combines self-supervised pretraining with semi-supervised transformer-based detection. First, we use Masked Image Modeling (MIM) on 1098 CT volumes to pretrain a 3D U-Net encoder for anatomical representation learning. Next, we adapt V-DETR to dense volumetric CT through a feature adapter that converts the encoder feature grid into a compact token sequence for transformer decoding. The pretrained encoder is then integrated with V-DETR and 3D Vertex Relative Position Encoding (3D V-RPE) to improve the localization of irregularly shaped injuries. Finally, semi-supervised teacher–student consistency regularization leverages 2,000 additional unlabeled volumes during detector training. To the best of our knowledge, this is the first application of a 3D DETR-style detector to the RSNA abdominal trauma detection task. On this benchmark, the proposed method achieves 31.33% test mAP@0.50 using only 78 labeled training volumes, corresponding to a 1.53× improvement over supervised-only training. These results show that combining medical-domain pretraining with semi-supervised learning is an effective strategy for label-scarce 3D medical detection.

Abstract

High breast density is a known risk factor for breast cancer. Current gold standard methods of density measurement are highly variable, and as such, reporting of density is not standard practice worldwide. The use of artificial intelligence has shown promise, but a lack of a definitive ground truth leads to less reliable predictions. This work combines artificial intelligence with spectroscopic X-ray imaging, which preserves compositional tissue information, as a novel density estimation method. A proof-of-concept study was performed by simulating the breast imaging process for breast tissue-equivalent phantoms to build a training set for a custom machine learning tool. This gave good results, having a mean squared error in the model's output of 0.013 +/- 0.002 %. Based on these results, further work focused on increasing the realism of the simulation and training data by modelling the charge transport in the detector as well as including anthropomorphic breast phantoms. This work will provide the foundations towards building a reliable and accurate way to measure breast density, allowing early cancer detection by tailoring patient pathways, and improving health outcomes.

Abstract

The positron range (PR) is a fundamental resolution-limiting factor in positron emission tomography (PET), particularly for high-energy radionuclides such as ^{82}Rb. In cardiac PET, the long PR of ^{82}Rb causes spatial blurring, activity spill-out, and reduced myocardial contrast, especially across heterogeneous tissue interfaces. Deep learning-based PR correction (PRC) provides a practical post-reconstruction strategy, but supervised regression networks often produce over-smoothed outputs by attenuating high-frequency stochastic fluctuations. We propose a model-consistent framework that decouples structural PR correction from texture preservation by combining PRC, matched smoothing estimation, and deterministic texture reinjection. In simulated ^{82}Rb PET studies, the proposed framework improved the recovery coefficient by 13.8% relative to the uncorrected ^{82}Rb input, while restoring noise levels closer to the reference (9.74 ± 1.85% vs. 10.62 ± 0.82%), supporting structure–texture decoupling as a promising strategy for PET imaging.

Abstract

This paper presents a genetic-algorithm-inspired methodology for denoising positron emission tomography (PET) sinograms from a single noisy acquisition. The method assumes that a noise-free sinogram (NFS) is embedded within the noisy sinogram (NS) and formulates denoising as the search for chromosome-encoded parameters capable of recovering it. Each chromosome generates a candidate NFS by fitting continuous exponential curves to the measured sinogram data, with the exponential order and other generation parameters encoded in a reduced-size chromosome. For each candidate, the residual noise is computed as the difference between the NS and the generated NFS. The selection criterion is based exclusively on the statistic al properties of this residual noise, without requiring a ground-truth image or supervised training data. Since PET measurements are governed by photon-counting statistics, the residual noise is expected to exhibit Poisson-like behavior. Accordingly, the fitness function evaluates the mean-to-variance ratio over homogeneous count regions obtained by percentile-based stratification of the residual noise map. A ratio close to 1.0 indicates consistency with Poisson statistics. Experiments on simulated brain phantoms show a strong correlation between this noise-statistical criterion and the inverse of PSNR and SSIM after filtered back-projection reconstruction. These results indicate that chromosomes whose residual noise better satisfies Poisson statistics tend to produce higher-quality reconstructed images. The proposed method therefore provides a reference-free and interpretable framework for PET sinogram denoising, reducing dependence on annotated datasets and offering a mathematically evaluable alternative to supervised deep-learning approaches.

Abstract

The choice of cross-validation (CV) strategy can significantly affect reported performance in deep learning studies, but systematic comparisons of CV methods for medical image classification remain limited. This study systematically benchmarks seven common cross-validation strategies across nine mainstream deep learning models and a logistic regression baseline to classify major adverse cardiac events (MACE) utilising stress-phase PET MPI polar map data. For each model and CV combination, evaluated on identical data splits, we report average precision (AP) and area under the receiver operating characteristic curve (AUC) as primary metrics, with confidence intervals estimated by bootstrapping. Quantitative analysis shows that Stratified Shuffle consistently yields the highest and most stable AP and AUC scores, exemplified by SqueezeNet achieving an AP of 0.52, AUC of 0.85, and delivering reduced variability across models compared to the bootstrap approach. These results highlight the critical impact of CV strategy on reliable and reproducible model evaluation for imbalanced and limited-size biomedical datasets.

Abstract

Optimizing detection efficiency and angular resolution in Compton cameras (CC) remains a challenge for its use in nuclear medical imaging of targeted alpha therapy (TAT) and prompt-gamma (γ) Positron Emission Tomography (PET) isotopes. A trade-off between detection efficiency and angular resolution must be considered when designing scattering layer material, thickness, and distance to the absorbing layer. We propose a novel approach by repurposing a cross-strip edgeon Cadmium Zinc Telluride (CZT) PET detector system as a high-sensitivity, single-layer CC. By leveraging 40 mm of CZT thickness and binning coincidences based on scattering distance, the system functions as a virtual multi-stage CC within a single volume. GATE simulations of γ's from 137Cs (662 keV) and 133Ba (356 keV) yield event sensitivities up to 4,508±7 and 1,239±4 cps/MBq and angular resolutions of 10.8° and 16.3° respectively. This work demonstrates the advantages of high energy resolution edge-on CZT, operating as a dual-mode PET/CC, providing a high-sensitivity where angular resolution can be further enhanced without sacrificing sensitivity. Future work aims to improve the existing design with advanced reconstruction algorithms, depth-of-interaction (DOI) correction, and detector optimization.

Abstract

A new microscopic nuclear imaging instrument using radioluminescence microscopy (RLM) has been developed to image living cells at high resolution with radiotracers tagged with positron emitters. These are used in biological samples to mimic clinical applications in order to evaluate their effectiveness to target receptors, antigens, and proteins that are overexpressed during growth of cancerous cells. The methodology has demonstrated impressive results for planar applications using optical reconstruction of β-ionization tracks (ORBIT); however, 3D imaging presents a challenging problem of reconstructing the 3D distribution of the source requiring backtracking of the ionization track of the positron in the scintillator in order to determine its position and 3D orientation at the detector surface. Four microlens arrays are used to record projections, limiting the angle of projection measurements to 360° sampling in the azimuthal angle φ and 40° sampling in the polar angle θ. The angle information acts as a collimator but the limited angle acquisition presents a challenging reconstruction problem which increases in difficulty for sources further from the scintillator. We consider reconstruction of the image x as a hierarchical maximum a posteriori (MAP) estimation problem under a Poisson data model with a total variation (TV) prior. In our algorithm we treat the prior weight β as a variable and jointly estimate x and β by minimizing the sum of the negative Poisson log-likelihood and a TV penalty. An alternating optimization scheme is used in which x is updated by MAP-TV reconstruction and β is updated from the current image total variation using a deviance-based adaptive update method. Good results are demonstrated using Geant4 simulations of point sources as far as 98 μs from the face of the detector. The novelty is the microscopy application to image individual cells three-dimensionally with radiopharmaceuticals.

Abstract

X-ray fluorescence computed tomography provides element-specific imaging, but weak fluorescence peaks are often obscured by a broad Compton-scatter continuum in photon-counting spectra. The objective of this study was to improve fluorescence projection extraction before reconstruction by replacing local empirical background fitting with a physics-informed hierarchical full-spectrum unmixing method. Each measured spectrum was modeled under Poisson counting statistics as the sum of a Klein--Nishina-constrained scatter template and a calibrated fluorescence-line template. The estimator was built hierarchically, progressing from pixel-wise spectral fitting to detector-plane joint unmixing and cross-angle projection-stack refinement. The method was evaluated on a simulated polymethyl methacrylate phantom with known fluorescence projections and on an experimental spectral data set. Under the default simulated Poisson-noise setting, the proposed method reduced projection root-mean-square error from 7.98 to 3.54 and background standard deviation from 3.92 to 1.39 relative to polynomial background extraction. On experimental data, it achieved the lowest contrast-to-noise-ratio-based detection limit, 0.305 mg/ml, compared with 0.370 mg/ml for polynomial extraction. These results indicate that structured full-spectrum unmixing can improve weak fluorescence extraction and downstream detectability while remaining compatible with existing reconstruction pipelines.

Abstract

[^{18}F]FDG and [^{11}C]choline ([^{11}C]CH) are used in hepatocellular carcinoma (HCC) lesions for more accurate characterization across various differentiation stages. In this study, we investigate a simultaneous dual tracer protocol, in which [^{11}C]CH is administered immediately following [^{18}F]FDG scanning, and assess whether dual tracer images can provide diagnostic information comparable with single tracer [^{18}F]FDG and [^{11}C]CH. We simulated single and dual tracer datasets to evaluate the impact of residual [^{18}F]FDG activity on [^{11}C]CH quantification. Realistic activity distributions were used, and lesions of varying sizes (1–4 cm) were inserted in the liver and spleen with different tumor-to-background ratio (TBR) uptake patterns. Analytic simulations were performed using STIR library for a long axial field-of-view PET scanner. Results indicated that all lesions remained detectable in dual tracer images, and TBR preserved differentiation dependent patterns. Averaged relative differences and standard deviation for SUV_{mean}, SUV_{max} and SUV_{peak} between the dual tracer and [^{11}C]CH images were -21.1±10.5%, -22.5±10.6% and -18.0±8.2%, respectively. To improve quantification, voxel-wise [^{18}F]FDG subtraction was applied as a separation step, reducing the mean absolute relative difference to 1.2±1.1% for SUV_{mean}, 4.4±4.1% for SUV_{max} and 1.2±1.08% for SUV_{peak}. These results demonstrate the clinical feasibility of a dual tracer [^{18}F]FDG:[^{11}C]CH imaging protocol and motivate further optimization of separation methods for simultaneous dual tracre clinical implementation.

Abstract

The Nuclear Plasma Science Society (NPSS) Educational Committee (EduCom) oversees educational initiatives and manages the NPSS Schools as its main vehicle for sustainable education. One such initiative is the EduPET project, which aims to develop an educational system to be used in EduCom's instrumentation schools. The EduPET system was designed to demonstrate the fundamental principles of Time-of-Flight Positron Emission Tomography (ToF-PET) using modern detector instrumentation. The current prototype consists of two opposing detector modules, each comprising a 2×2×30 mm^3 LYSO:Ce crystal coupled to a Hamamatsu S13360-2050 silicon photomultiplier (SiPM), with signal digitization performed by a DRS4-based WaveDREAM board. Initial measurements included energy spectroscopy, coincidence timing, and ToF-based source localization using a ^{22}Na point source positioned at multiple locations along the detector axis. Coincidence time resolution (CTR) values ranging from 463 to 591 ps FWHM were obtained across the different positions. The timing resolution achieved was sufficient to resolve source displacements and demonstrate the probabilistic nature of ToF-based position estimation, confirming the suitability of EduPET system as an effective educational platform for illustrating key ToF-PET concepts and advanced instrumentation techniques. Future developments will focus on expanding the detector geometry toward a complete tomographic system.

Telephoto-Lens Magic-Cube: A Hybrid-Encoded Portable Gamma Camera for Extended-Distance Intraoperative Radiotracer Imaging

(#2251)

Abstract

Intraoperative radiotracer imaging requires gamma cameras to maintain adequate imaging performance at relatively large source-to-camera distances, because surgical targets are often separated from the detector by tissue, instruments, surgical access constraints, or sterile operating space.

In this work, we propose a Telephoto-Lens Magic-Cube gamma camera based on a hybrid encoding mechanism. The proposed system integrates front-end long-hole geometric encoding with detector-side self-collimation encoding, allowing distant radioactive sources to generate distinguishable detector responses.

The proposed system was evaluated using numerical simulations and radioactive-source prototype experiments. In simulations, the Telephoto-Lens Magic-Cube maintained better spatial resolution at large source-to-camera distances than the Magic-Cube system without the Telephoto-Lens and two conventional parallel-hole collimator systems. It also successfully detected low-activity hot spots under background activity at large distances, whereas the reference systems failed to provide reliable detection. Prototype experiments demonstrated a mean sensitivity of 118 cps/MBq over 50–200 mm, dual-source resolution of 3 mm at 100 mm and 5 mm at 150 mm, and accurate lateral localization of 10 μCi point sources. In an anthropomorphic prostate lymph-node phantom, the system visualized five low-activity deep lymph-node-like sources under background activity and organ-uptake interference. These results suggest that the hybrid-encoded Telephoto-Lens Magic-Cube gamma camera is promising for intraoperative localization of deep low-activity lesions or lymph nodes.

Abstract

Whole gamma imaging (WGI) is a novel imaging concept combining both PET and Compton camera using a dual-ring detector arrangement. We previously developed a series of WGI prototypes for proof-of-concept. In WGI Prototype IV (WGI-IV), reported in 2025, we targeted imaging of 909 keV γ-rays from ^{89}Zr, achieving a 3.0-mm rod resolution by Compton imaging. In this study, we aimed at further improving Compton imaging performance by using thin scatterer detectors, considering a potential extension to typical SPECT tracer imaging, and we developed WGI Prototype V (WGI-V). Compton imaging performance is determined mainly by the spatial resolution and energy resolution of scatterer detectors. Therefore, we used fine and thin 0.9×0.9×2.0 mm^3 HRGAGG scintillators to obtain high spatial resolution and high energy resolution. The outer absorber ring (304 mm diameter), which was composed of 216 fast-LGSO crystal blocks, was the same as that in WGI-IV. The inner scatterer ring (109.4 mm diameter) was remodeled with 10 HRGAGG crystal blocks (22×22 array). We evaluated energy resolution for scatterer detectors using ^{133}Ba, ^{241}Am, ^{99m}Tc and ^{176}Lu (background). Then, we evaluated small rod resolution using a ^{89}Zr-filled rod phantom (rod diameters: 1.0-4.8 mm). Energy resolutions for scatterer detectors were 37.6% at 31 keV, 27.3% at 59.5 keV, 21.5% at 81 keV, 15.0% at 141 keV, and 7.5% at 307 keV. These were superior to those for the previous scatterer detector (HRGAGG, 1.45×1.45×15 mm^3, 14×14 array). In the ^{89}Zr-filled rod phantom measurement, the 2.2-mm rods were resolved by WGI-V, whereas they could not be resolved by WGI-IV. High-resolution Compton imaging (2.2-mm rod resolution) was achieved by WGI-V with 0.9×0.9×2.0 mm^3 HRGAGG scatterer detectors. An application of the WGI-V to SPECT tracers will be presented at the conference.

Abstract

The measurement of the three-photon to two-photon annihilation rate ratio ($R_{3\gamma/2\gamma}$) in positronium decays emerges as a promising diagnostic indicator for accessing tissue hypoxia [1, 2, 3]. The triplet state of positronium (ortho-positronium) is highly sensitive to local molecular oxygen concentrations [4, 5]; thus, the $R_{3\gamma/2\gamma}$ ratio could reflect on the oxygenated level of tissues [6, 7]. This study presents methodology for determining the absolute values of this annihilation ratio using the Jagiellonian Positron Emission Tomograph (J-PET), the first PET scanner based on plastic scintillators [8]. We performed measurements with sodium-22 source enclosed in metal to characterize the detector response and geometrical acceptance for the $R_{3\gamma/2\gamma}$ ratio. Since the positronium formation is suppressed in metals the resulting annihilation ratio serves as a detector-dependent reference value. After calibrating with sodium-22 in metal, we have performed the studies with porous polymer material where the positronium formation is enhanced. The two-photon and three-photon annihilation events selection are described, and their respective lifetime distributions are presented. The results presented validate the event selection methodology and establish the detector calibration baseline for future quantitative $R_{3\gamma/2\gamma}$ studies in biological sample with J-PET.

Abstract

Compton cameras (CCs) can be designed as compact and portable systems that can be employed in combination with other imaging modalities. These imaging systems provide 3D images with just one device. However, the resolution in the axis perpendicular to the first detector is degraded with respect to the parallel plane, especially at positions far from the detectors. Placing two CCs orthogonally can improve the uniformity of the 3D spatial resolution and also increase the usable size of the field of view (FOV). Following an initial study based on simulations carried out by the IRIS group, the current work aims at an experimental verification of operating two CCs positioned orthogonal to each other in the dual-CC MACACOX2 system. In this work, simulations are performed using a geometry that replicates the laboratory setup. Coincidence data are simulated with sources located at the center of the geometry, such that the scatterers of both CCs are positioned 30 mm from the center of the FOV. The image reconstruction algorithm has been developed and optimized by the group specifically for this imaging modality and is being applied in this work. Images of a ^{22}Na point source array obtained using the simulated two head CC system and reconstructed at 511 keV are obtained. Point sources separated by 8 mm can be clearly resolved at two, three, and four cm from the detector surface. Such successful findings provide foundation for the ongoing laboratory experiments with the MACACOX2 system.

Abstract

Medical thermal imaging has long been explored as a non-invasive diagnostic modality for detecting localized sub-surface abnormalities associated with pathological processes. However, despite decades of investigation, conventional thermography has not achieved widespread clinical acceptance due to inconsistent and unreliable results. In this work, we experimentally validated a framework for medical thermal tomography combining high-precision thermal measurements in a controlled and monitored environment with physics-informed tomographic reconstruction. Following software-phantom studies, the methodology was validated using a dedicated automated experimental setup together with a suite of calibrations and temporal and spatial corrections, reducing the uncertainty in panoramic thermal projections to approximately 25 $^{\circ}$C. Reconstruction was performed using physics-informed forward thermal diffusion models within the AMIAS/RISE framework. Using this methodology, localized hot-spots with temperature differences as low as ΔT = 1.5 $^{\circ}$C were successfully detected and reconstructed at depths up to 3.3 cm in hardware phantoms. The reconstructed positions and temperatures were in good agreement with independent thermocouple and µCT measurements. These results provide strong evidence that thermal tomography is feasible when combined with precision thermal measurements and physics-informed reconstruction methods.

A Computational Assessment of Quantum SimulationVersus Classical Simulation for Quantum-InspiredMedical Imaging (#3117)

Amirreza Hashemi, Hamid Sabet

Massachusetts General Hospital, Harvard Medical School, Radiology, Boston, USA

This work was supported in part by NIH grant R01EB034785

Abstract

Quantum-inspired formulations have emerged as a promising approach for medical image denoising and segmentation by recasting image processing tasks as eigenvalue problems. While computationally demanding on classical hardware, these methods align naturally with quantum computing paradigms, particularly the Variational Quantum Eigensolver (VQE). In this work, we assess whether quantum simulation on classical hardware is justified in the absence of real quantum devices by comparing classical computing (CPU-based diagonalization), quantum simulation on CPU, and GPU-accelerated quantum simulation using Qiskit. Experiments on synthetic data and a clinical PET/CT case show consistent reconstruction and segmentation quality across implementations. Quantitatively, classical methods are faster for small problems (e.g., 0.0063 s vs 0.0229 s), while GPU-based quantum simulation reduces this gap (~0.003 s) and becomes slightly faster at larger scales (660.78 s vs 669.1 s). These results indicate that quantum simulation is not advantageous for small cases, but can become competitive or beneficial for larger problems within a quantum-inspired framework.

Minkhole Collimators for SPECT: Minkowski-Sum Aperture Geometry and Closed-Form Ray Tracing (#1605)

Yusheng Li[1], Hongdi Li[1]

[1] United Imaging Healthcare North America, MI, Houston, USA; [2] United Imaging Healthcare North America, MI, Houston, USA

Abstract

Single-photon emission computed tomography (SPECT) pinhole collimators trade isotropic resolution against detector coverage: circular apertures cover only 78.5% of a square detector. Rectangular pinholes (rectholes) fill the detector but introduce anisotropic resolution. Lofthole collimators linearly interpolate between a circular aperture and a rectangular exit; their non-developable lateral surfaces complicate fabrication and geometric calibration. We present the minkhole collimator, a knife-edge geometry whose half-frustum equals the Minkowski sum of a circular waist and a rectangular exit. The half-frustum boundary decomposes exactly into ten analytic patches: two caps, four ruled side planes, and four corner quadrics. Convexity of each half-frustum bounds a ray to at most two boundary intersections, giving a closed-form ray tracer of six linear and four quadratic solves with no iteration. We implement the 10-patch intersection and compare the minkhole to pinhole, recthole, and lofthole collimators on a common geometry. At matched sensitivity and field of view, minkhole projections are more symmetric than the recthole's and show less diagonal elongation than the lofthole's, while fully covering the detector. Its piecewise-developable surface (planar and sheared-conical patches) admits a compact analytic form that simplifies calibration, making the minkhole a practical building block for multi-aperture SPECT.

The authors want to warmly thank all the team at Spectrum Dynamics, Justine McQuillan and Raphael Blum for very thorough discussions. M. Erojo would like to acknowledge that her work is supported by the Finnish Ministry of Education and Culture's Pilot for Doctoral Programmes (Pilot project Mathematics of Sensing, Imaging and Modelling).This work was performed within the framework of the SIRIC LYriCAN Grant INCa-DGOS-INSERM-ITMO cancer_18003, the LABEX PRIMES (ANR-11-LABX-0063) of Université de Lyon, within the program 'Investissements d'Avenir' (ANR-11-IDEX-0007) operated by the ANR.

Abstract

The aim of this study was to develop and evaluate a GATE Monte Carlo model of the ring CZT based VERITON SPECT-CT system against experimental data. System spatial resolution was evaluated using planar images with ^{99m}Tc point-like sources. Good agreement was obtained between both experimental and simulated data with consistent values within one sigma, except for the studied distances closest to the collimator surface (5 and 7 cm) where relative discrepancies of 25% and 7% were observed along X-axis. A tomographic acquisition, corresponding to 4 gantry rotations and 60 swivel positions per detector head, using the NEMA IEC body phantom was simulated within GATE 10. A qualitative comparison of profiles showed good agreement between both reconstructions.

We plan to further evaluate this model regarding quantitative imaging and extend it to additional radionuclides. Such a model could have a significant impact on the optimisation of acquisition protocols, image reconstruction and system design.

Intraoperative Position-Sensitive Positron Emission Counter (PEC): A Simulation Study (#2337)

Ryotaro Ohashi[1,2], Shigeki Ito[3], Miwako Takahashi[1], Taiga Yamaya[1]

[1] National Institutes for Quantum Science and Technology, Chiba, Japan; [2] Chiba University, Graduate School of Science and Engineering, Chiba, Japan; [3] Mirai-Imaging Corporation, Fukushima, Japan

Abstract

For metastatic lymph-node localization in esophageal cancer surgery with ^{18}F-FDG injection, we have been developing an intraoperative positron emission counter (PEC). This device employs two BGO scintillators (~10×5×15 mm^3) on the tip of a forceps and it provides coincidence detection. The current design of the PEC is not position sensitive; however, quantitative radioactivity measurement requires recovery of the source distribution within the compact field of view (FOV) of the PEC, because position-dependent detection efficiency renders the integral count rate ambiguous. In this paper, we investigate the feasibility of source distribution visualization on a position-sensitive PEC variant featuring 2×2 segmentation of each scintillator (yielding 16 lines of response, LORs) together with a machine-learning (ML) decoder mapping these 16 LORs to a source distribution. Specifically, we designed a multi-layer perceptron (MLP) with a spatial-softmax head defined over the FOV. The MLP was trained with Kullback-Leibler (KL)-divergence supervision on random-walk phantoms (each yielding a 16-LOR expected count vector via Geant4 simulation, Poisson-sampled at a 100-count budget), with mixed single- and synthetic 2-source training samples. The pitch of the FOV reconstruction grid was 0.5 mm. On held-out single-source test phantoms, the predicted distribution provides the source center-of-gravity (CoG) with a median 3D Euclidean mean-absolute-error (MAE) of 0.73 mm and the per-axis source extent within ≤16% (sigma MAE 0.13–0.24 mm vs. ground-truth 1.2–1.5 mm). On disjoint 2-source pairs, 90.1% of the detected peaks lie within 2.5 mm of a true source (per-detected-peak median 1.40 mm; per-true-source median 1.58 mm). These results indicate that a position-sensitive PEC with an MLP-based decoder achieves not only the source localization but also the source distribution visualization from only 16 LOR counts.

A metascintillator-based, ultra-ToF enabled, brain PET scanner simulation (#2563)

Georgios Konstantinou[1,2], Paul Lecoq[2,3]

[1] EPFL, PV lab, Neuchatel, Switzerland; [2] Metacrystal SA, Geneve, Switzerland; [3] CERN, Geneve, Switzerland

Abstract
Metascintillator systems composed of LYSO:Ce and 2D organic lead halide perovskites were recently measured in the laboratory with high end electronics. The timing behavior of this metascintillator rendered two dominant subsets: 44% of fast, perovskite-led and shared events at 46 ps and 56% of slow, LYSO:Ce events at 110 ps. As this design reaches ultrafast ToF regimes, an opportunity to better understand the effect of such CTR on final image quality arises. The possibility of adapting this configuration to a photonic-driven semi-monolithic metascintillator also offers very good depth-of-interaction discrimination, at 4 mm. To benchmark this detector architecture, a brain PET scanner was designed in GATE, with a Hoffman brain and Derenzo phantoms for benchmarking. A series of reconstruction approaches, for instance using the fast subset as priors or weighing in on the different subsets been performed, but the drive for this exercise is to invite the reconstruction community to experiment with and demonstrate the potential of new generation high end ToF detectors for medical imaging.

MIC-06-05

Towards the Ultimate Sub-0.4 mm Resolution: GATE Simulation of a Mouse Brain PET System (#1832)

Han Gyu Kang, Hideaki Tashima, Taiga Yamaya

National Institutes for Quantum Science and Technology (QST), Advanced Nuclear Medicine Sciences, Chiba, Japan

This work was partly supported by 2023 IEEE Edward J. Hoffman Early Career Development Grant.

Abstract
Last year, we developed a sub-0.5 mm resolution positron emission tomography (PET) system using staggered 3-layer depth-of-interaction (DOI) detectors for mouse brain imaging. However, the crystal pitch of 0.8 mm limited the spatial resolution to 0.45 mm, which sparked our pursuit of the ultimate resolution. In this study, we investigate the spatial resolution of a newly proposed mouse brain PET system that uses a reduced crystal pitch as we move towards sub-0.4 mm resolution. The proposed system provides 48 mm inner diameter and 22.6 mm axial coverage. It consists of 32 DOI detectors with 2-ring geometry. Each DOI detector has staggered 3-layer LYSO crystals

(crystal pitch=0.6 mm) with a crystal layer thickness of 3+3+5 mm, thereby providing a 11 mm total thickness. We used GATE simulation to investigate the performance of the proposed PET design. For spatial resolution evaluation, an NEMA ^{22}Na source (D=0.25 mm) was scanned from the field-of-view center to the 15 mm radial offset position and it was reconstructed by using an FBP algorithm. For imaging performance evaluation, a resolution phantom having six different rod diameters was used. The PET images were reconstructed by using the OSEM algorithm. Compared to results of our previous work, the spatial resolution was improved from 0.75±0.02 mm to 0.55±0.07 mm. Unlike the previous work, the 0.4 mm rods of the resolution phantom were resolved with a valley-to-peak ratio of 0.763. In conclusion, the simulation showed that our proposed mouse brain PET system provided 0.4 mm resolution in resolution phantom imaging. As a next step, we plan to develop a prototype mouse brain PET scanner to achieve 0.4 mm resolution experimentally.

Experimental Feasibility of Dual-Mode C-arm CT/SPECT Imaging Using a Commercial X-ray Detector for Online Brachytherapy Delivery Verification (#1805)

Saerom Sung[1], Hyun Joon Choi[2], Sangwoon Jeong[2], Sei Hwan You[2], Chul Hee Min[1]

[1] Yonsei University, Department of Radiation Convergence Engineering, Wonju, South Korea; [2] Yonsei University Wonju College of Medicine, Wonju Severance Christian Hospital, Department of Radiation Oncology, Wonju, South Korea

This work was supported by NRF/MSIT, Republic of Korea (RS-2025-25438965), and the Gangwon RISE program (2025-RISE-10-006).

Abstract

Online brachytherapy delivery verification requires two complementary capabilities: anatomical verification of the applicator prior to irradiation and dynamic tracking of the radioactive source during dose delivery. This study experimentally evaluated the feasibility of a dual-mode C-arm CT/SPECT imaging concept using a single commercially available X-ray flat-panel detector. The core paradigm repurposes a standard X-ray detector into a shared hardware platform: an uncollimated mode for structural visualization, and a collimator-attached mode for radioactive source tracking. The experimental setup utilized a DRTECH EXT1616R digital detector. In the uncollimated X-ray mode, projection images of a PMMA–agar phantom containing a two-ovoid applicator were acquired at 90 kV and 10 mAs during rotational acquisition. The acquired projections successfully distinguished the applicator, air cavities, and phantom tissue surrogate layers. For the SPECT mode, a parallel-hole tungsten collimator was attached to the identical detector. Projection frames of a 58.12 GBq Co-60 source were acquired continuously at 1 frame/s during rotation. Following image intensity enhancement, the Co-60 source profile yielded full width at half maximum values of 3.80 mm and 2.91 mm in the x and y directions, respectively. Furthermore, to demonstrate the ultimate clinical utility of this dual-mode concept, a high-quality reference CT image of a patient-specific 3D-printed pelvic phantom was overlaid with the reconstructed SPECT source distribution, successfully illustrating CT/SPECT fusion feasibility. These findings robustly support the experimental viability of utilizing a commercial X-ray detector for both anatomical assessment and frame-based source delivery verification.

Abstract

This study explores nuclear medicine imaging toward visualization of both radiotracer distribution and microscopic chemical environment using ^{111}In cascade gamma-ray correlation. PAC coefficients of ^{111}In-labeled agents were quantitatively evaluated under different pH conditions to assess local chemical-environment sensitivity. Cell experiments using ^{111}In-labeled molecular probes were performed to examine applicability to biological samples. In vivo DPECI visualized ^{111}In-labeled agent biodistribution in mice, showing liver and tumor signals consistent with ex vivo organ biodistribution. These results provide a basis for future multimodal imaging that integrates PAC-derived microscopic chemical information with DPECI-based spatial visualization.

Abstract

In presurgical epilepsy evaluation, noninvasive localization remains challenging in patients with negative or suspicious magnetic resonance imaging findings or inconsistent multimodal results. Positron emission tomography provides metabolic information, while electroencephalography records abnormal electrical activity. However, conventional fixed PET systems usually require supine and constrained positioning, limiting simultaneous monitoring during seizure-related states, task conditions, or near-natural behaviors. To address this limitation, we integrated scalp electroencephalography with an ultra-light wearable motion-following brain PET system to evaluate the feasibility of simultaneous metabolic-electrophysiological imaging in epilepsy subjects. Compatibility was first assessed using an electroencephalography-equipped brain phantom. Phantom images acquired with and without electroencephalography electrodes showed comparable structures, and electroencephalography waveforms remained interpretable with and without PET operation. Initial human evaluation was then performed in an epilepsy patient. Wearable brain PET imaging and simultaneous wearable PET/EEG acquisition were successfully completed. During prolonged acquisition, the subject fell asleep, causing detector displacement and motion artifacts in reconstructed PET images. These results demonstrate the technical feasibility of simultaneous wearable metabolic-electrophysiological brain imaging and highlight the need for improved fixation, motion tracking, and motion correction in future natural-state neuroimaging studies.

Human Subject and Phantom Imaging Performance of PETcoil Gen II Brain-Dedicated PET System (#2894)

Grant H.-S. Park, Muhammad N. Ullah, Garry Chinn, Craig S. Levin

Stanford University, Radiology, Stanford, USA

This work was supported in part by NIH-NIBIB grant #5R01EB03103804. The authors thank Dr. Qian Dong for foundational contributions to the PETcoil Gen II system, Martin Schneider, our clinical coordinator for this study, and the patient who participated in this first clinical scan.

Abstract
PETcoil Gen II is a second-generation RF-penetrable time-of-flight (TOF) positron emission tomography (PET) brain insert designed for simultaneous PET/MRI. We evaluated initial imaging performance using a 3D Hoffman brain phantom and present the first clinical ^{18}F-FDG brain PET images acquired with the system. Randoms correction was performed using delayed-window (DW) estimates. A computed tomography (CT)-based attenuation

(μ) map was generated and extrapolated to 511 keV using piecewise linear interpolation, while scatter fractions were estimated via OpenSSS. In the Hoffman phantom and research subject scan, full corrections improved signal-to-background ratio from 3.48 to 4.50 and from 2.69 to 3.20, respectively, with improved visualization of cortical and subcortical structures. These results indicate that the correction methods are functioning and demonstrate the ability of the PETcoil Gen II to produce high-quality images.

Development of SIAT 9.4T MRI compatible animal PET scanner (#1791)

Haonan Li, Hui Huang, Sen Yang, Zhonghua Kuang, Ning Ren, Zhanli Hu, Yongfeng Yang, Zheng Liu

Chinese Academy of Sciences, Paul C. Lauterbur Research Center for Biomedical Imaging, Shenzhen Institute of Advanced Technology, Shenzhen, China

This work is supported by the National Key Research and Development Program of China (2023YFF0716000), the National Natural Science Foundation of China (Grant No. 12375358), the Shenzhen Science and Technology Program (JCYJ20220531100000001, JCYJ20220818101804009).

Abstract

This study aims to develop a 9.4 T MRI-compatible small-animal PET insert with sub-millimeter spatial resolution and system-level magnetic compatibility. The PET insert consists of 84 dual-ended readout detector arrays arranged in 7 axial rings, with 12 detector modules per ring. Each detector array contains a 28 × 28 LYSO crystal matrix with a crystal size of 0.75 × 0.75 × 20 mm³. Compact front-end amplification electronics, row-column multiplexed readout, non-magnetic mechanical support, and inner/outer carbon-fiber tubes were integrated to meet the spatial and electromagnetic compatibility requirements of a 9.4 T MRI scanner. Point-source imaging was performed to evaluate spatial resolution. A prototype PET insert was developed and integrated. ^{22}Na point-source images reconstructed using OSEM with 5 iterations demonstrated sub-millimeter spatial resolution, indicating high-resolution imaging capability for 9.4 T small-animal PET/MRI applications.

Abstract

Spatial normalization enables standardized volume-of-interest quantification in brain perfusion single-photon emission computed tomography, but accurate alignment is difficult because of low resolution, noise, partial volume effects, and uptake-dependent variation. We propose a MRI-informed, SPECT-only framework that distills anatomical deformation fields and feature guidance from a magnetic resonance imaging registration teacher. The student disentangles anatomical and uptake-related representations to suppress functional-uptake interference while requiring only single-photon emission computed tomography at inference. In 173 paired imaging datasets, the method improved standardized uptake value ratio consistency between subject and template spaces, especially for fine-grained volumes of interest, supporting MRI-free, single-pass template-based quantification.

Developments in fabrication and design flexibility of amorphous silicon microchannel plates (#2584)

Georgios Konstantinou, Loris Barraud, Christophe Baillif, Nicolas Wyrsch

EPFL, Neuchatel, Switzerland

The project is funded by the SNF SPARK grant no CRSK-2_237272

Abstract

The technology of amorphous silicon-based micro-channel plates (AMCPs) uses a versatile approach to stack hydrogenated amorphous silicon in thicknesses up to 100 µm, using plasma-enhanced chemical vapor deposition (PECVD) and etch microchannels of diameter below 2 µm every 5 µm, on a hexagonal pattern, by deep reactive ion etching. With gains up to 1000 for reverse bias less than 300 V, the design is possible to build on arrays of sensitive transimpedance amplifiers, integrated in read-out circuits with high channel density, such as for instance 15 by 15 µm. This ensures single photon detection with quantum efficiency up to 30% and noise rates below 50 Hz/cm², if combined with state of the art photocathodes such as the hi-QE from Photonis. Current fabrication runs focus on direct integration of the stack on ASICs, to be integrated with the photocathode over the next months. Measurements show timing response with jitter below 10 ps, making this high-precision photodetector ideal for radiation detectors combining ultra-fast photon emission and low light yield, such as Cherenkov.

Fabrication of diamond detectors with graphitic contacts for tissue equivalent dosimetry (#2040)

Ivan Lopez Paz, **Ivan Lopez Paz**, Consuelo Guardiola, Consuelo Guardiola, Gemma Rius, Gemma Rius

Institut de Microelectronica de Barcelona (IMB-CNM, CSIC), Bellaterra, Spain

This work has been funded by the IMB-CNM (CSIC) TRIGGER projects PIACeD and CarDos4FLASH, supported by the ‘María de Maeztu Unit of Excellence’ accreditation (CEX2023-001397-M / AEI/10.13039/501100011033). This study was also funded RYC2024-050777-I project, financed by the MICIU / AEI / 10.13039/501100011033 and FSE+.

Abstract

Diamond-based dosimeters are popular for medical dosimetry in view of their fast response, radiation hardness and tissue equivalence. However, some design improvements to achieve better accuracy in signal readout and approach tissue equivalence are possible by the removal of the metallic contacts, sometimes covering the active area of said devices.

In this contribution, we explore the use of a simple processing and scalable solution to obtain non-metal, low Z electrical contact. Thus, the fabrication of diamond detectors with graphitic contacts at the Microelectronics Institute of Barcelona are shown. Several approaches are explored, some of which never utilised before for radiation detector fabrication, namely pyrolytic photoresist film, nickel catalysis and ion surface graphitisation.

A prototype of such device using the pyrolytic photoresist film process for the first time has been produced and was tested under a 60 kV X-ray tube. We report the fabrication and preliminary performance results of such device. Although the substrate material quality is not ideal for radiation detection, it was possible to observe radiation response using the PPF as an interface material. The prototype features a linearity better than 3% as tested in a laboratory X-ray chamber, proving it a promising technology for detector operation. Finally, the technology

challenges are finally discussed to assess the feasibility of PPF-diamond technology for dosimeter batch production.

This work was supported by the US NIH NIBIB through competitively awarded contracts number 4R44MH135525-02.

Abstract

Lutetium oxide–based scintillators are of growing interest for positron emission tomography (PET) because of their high density and high effective atomic number, which provide efficient stopping of 511 keV annihilation photons. Lanthanum-doped $(Lu,Y)_2O_3$ (LYO:La) is a transparent ceramic variant that retains the favorable stopping power of Lu_2O_3 while being easier to fabricate, making it an attractive candidate for next-generation PET detector arrays. In this work we report a scintillation characterization of LYO:La pixels in two geometries relevant to PET, 1×1×10 mm^3 for high-resolution preclinical and dedicated-organ imaging, and 3×3×10 mm^3 for whole-body clinical systems. Pixels were cut from LYO:La ceramic disks, polished on all faces, and evaluated with a range of side reflectors (Teflon, Tyvek, ESR film, and Spectralon) in both flat and upright coupling orientations. We measured X-ray-excited radioluminescence emission spectra, ^{22}Na (511 keV) pulse height spectra, relative light yield, energy resolution, scintillation decay time profiles, and timing resolution. The results illustrate the influence of pixel geometry, coupling face, and reflector choice on light collection and energy resolution, and show that LYO:La pixels offer a promising combination of stopping power, light yield, and timing performance for PET detector modules.

Ultrahigh Spatial Resolution Perovskite-based Direct X-ray Imagers for Low-lag Medical Applications (#3045)

Brandon Dunham[1], Shariar Motakef[1], **Amlan Datta**[1]

[1] CapeSym, Inc., Research and Developement, Natick, USA; [2] Massachusetts General Hospital, Department of Radiology, Boston, USA

This research was supported by the U.S. National Institutes of Health under award R44EB038123.

Abstract

Dynamic medical X-ray imaging requires detectors that combine high quantum efficiency, low residual lag, and high spatial resolution without the optical spread and afterglow of scintillator-based flat panels. We report a fully inorganic perovskite-based direct-conversion perovskite X-ray imager fabricated from phase-pure orthorhombic Cesium Lead Bromide (CPB) sensor material and integrated with active-pixel readout arrays. Phase-pure CPB was obtained by controlled crystal growth and converted into dense blade-coated films; non-phase-pure starting materials containing secondary phases produced nonuniform films and degraded images, confirming the importance of phase control for reproducible detector performance. The optimized CPB detector demonstrated high linear X-ray response, sensitivity of 55,400 μC $Gyair^{-1}$ cm^{-2} at 30 keV and 0.5 V/μm, a limit of detection of 417 pGyair s^{-1}, a mobility-lifetime product of 8.0×10^{-4} cm^2 V^{-1}, and a calculated detective quantum efficiency near 85% at practical dose levels. In flat-panel imaging, CPB imagers reached 6.9 lp/mm at 20% modulation transfer function on a 100 μm-pitch amorphous-silicon array and resolved 20 lp/mm after integration with a CMOS readout. Most importantly for low-lag medical applications, improvements in phase purity and charge-transport stability reduced residual detector lag from 8.9% to 1.1%. These results show that all-inorganic perovskite direct conversion can provide a path to low-dose, low-lag, high-resolution imaging for fluoroscopy, tomosynthesis, dental cone-beam computed tomography, and other image-guided procedures.

Abstract

Total-body positron emission tomography (PET) increases system sensitivity and enables whole-body dynamic imaging, but its extended axial field of view makes accurate depth-of-interaction (DOI) calibration essential for maintaining uniform spatial resolution and reducing parallax error. Conventional DOI calibration requires mechanically scanned collimated sources or detector-specific reference measurements, which become impractical as the number of detector modules increases. PhysiCal-PET introduces a physics-based neural-network framework for autonomous in-system DOI calibration of PET scanners. The method trains a network to map raw detector signals to DOI using coincidence data acquired with an uncollimated positron source at known positions. For each event, the loss function enforces annihilation geometry by requiring the predicted line of response to be consistent with the source position, thereby providing supervision without measured DOI labels. The framework was tested on realistic PET simulations and applied to data from a real preclinical PET scanner. Using this procedure, the DOI response of all 144 detector modules was calibrated in less than 2 hours of point-source measurement time. These results demonstrate that the annihilation physics can replace labor-intensive DOI calibration hardware and enable rapid, routine calibration of high-resolution PET systems. PhysiCal-PET therefore provides a scalable path toward autonomous calibration for total-body PET and other systems that rely on accurate DOI positioning. notionvc: 49ace5df-389b-489a-b611-1abe67c4c114

Abstract

A spatio-temporal denoising training strategy for low-dose fluoroscopy is proposed, based on a spatially-adaptive temporal consistency metric. This approach acts on a small set of consecutive frames coupling a conventional denoising operator with an adaptive motion-gradient attention gate to selectively modulate the temporal consistency terms within the loss function, ensuring effective noise suppression and flickering reduction while maintaining high anatomical fidelity in dynamic regions.
The proposed method was used to train a denoising operator in which a three-frame temporal window is used as input. The model was trained across multiple dose reduction factors (qF), and demonstrated superior structural recovery and enhanced temporal stability in the processed image sequences, compared to single-frame models. Quantitative and qualitative evaluation of image quality, along with stability maps—defined as the Normalized Cross-Correlation (NCC) of temporal Coefficient of Variation (CV) maps—confirms high fidelity relative to high-dose reference acquisitions, effectively mitigating stochastic fluctuations without introducing motion artifacts.

Abstract

Carbon-ion radiotherapy (CIRT) combines high biological effectiveness with outstanding treatment precision. Since treatment plans are based on the most recent Computed Tomography (CT), anatomical changes during multi-week treatments may compromise dose delivery accuracy. To address the increasing uncertainty about the patient's anatomical state with time elapsed since the planning CT, our group developed an in vivo monitoring method using secondary charged particles emitted during therapy. This non-invasive approach requires no additional dose and reduces uncertainty about patient anatomy and thus, loss of treatment accuracy. It uses a custom detection system to detect nuclear fragments emmited from the patient and allows approximating their origin. To reconstruct these changes in 3D, we utilize our recently published method for detecting the depth (z) of changes along the beam axis and apply it to a sliding window (x,y) along the transverse plane. However, splitting reconstructed nuclear fragment origins into smaller subsets reduces the statistical stability of each subset distribution. In this study, we present an approach to robustly distinguish whether a windowed subset belongs to a region with or without an anatomical change based on correlation matrices generated by our depth detection method. These images contain location-wise correlations of joined frequency band variations between projections of nuclear fragment measurements from different treatment days. To classify regions of change and approximate change depth, we train an ensemble of deep learning-based image classifiers with different architectures *(i.e. ResNet, RegNet and ConvNeXt)* and combine their outputs into an ensemble decision. The approach was validated using dedicated irradiation measurements with coin-sized cavities inserted into PMMA head phantoms. Despite limited training data, we achieved robust improvements in change localization using an ensemble of different deep learning architectures.

Zero-Shot PET Image Super-Resolution via Cross-Modal Mutual Information Guidance (#2526)

Yilin He, Yang Lv

Shanghai United Imaging Medical Technology Co., Ltd, Molecular Imaging Business Unit, Shanghai, China

This work was supported in part by Shanghai United Imaging Medical Technology Co., Ltd., through its internal research program. The authors gratefully acknowledge the Molecular Imaging team for their technical support and helpful discussions.

Abstract

Diffusion models have shown strong potential for improving PET image quality. However, existing methods based on unconditional pretrained diffusion priors often struggle to balance realism and fidelity, particularly in preserving high-resolution details. To address this issue, we propose MI-ResShift, a zero-shot mutual information-guided diffusion model with residual shifting for PET image super-resolution. MI-ResShift introduces a differentiable local-wise mutual information layer to guide the denoising process using structural information from CT or MRI, enabling robust cross-modal feature alignment in the statistical domain. By combining mutual information guidance with residual shifting, the proposed method enhances PET detail fidelity and robustness while reducing diffusion-based inference to only four steps. Experiments on PET/MR brain datasets demonstrate that MI-ResShift improves image quality over classical interpolation methods and provides an efficient solution for cross-modal PET super-resolution.

Abstract

Neural Network (NN) models have emerged as a promising tool for determining 3D photon impact positions in Positron Emission Tomography (PET) detectors based on monolithic scintillators. Nevertheless, NNs typically require long acquisitions of reference data training, becoming a time-consuming process that requires extensive experimental data for each individual detector module. To reduce calibration time, we propose a new methodology based on NNs trained entirely using simulated data to predict the 3D impact position of gamma rays. The feasibility of the proposed approach was verified using a real preclinical PET system composed of two rings of 8 LYSO:Ce monolithic scintillators each.

The simulation of a single detector was implemented in GATE and reference data moving a pencil beam in 1 mm steps was simulated to train two Multilayer Perceptrons (MLPs), MLP_X and MLP_Y, to predict the *x*- and *y*- impact positions, respectively. To validate the introduced methodology at reconstructed image level, experimental data was acquired using a ^{22}Na point source at the center of the preclinical system and processed using both the presented framework and the system's standard calibration methodology.

Results have demonstrated that similar spatial resolution was obtained with both approaches, thus demonstrating that NNs trained exclusively with Monte Carlo simulations can generate coherent reconstructed images and thus eliminate the need for calibration measurements for each individual detector module.

Abstract

Cell tracking in vivo is a key challenge in translational medicine. Positron emission tomography (PET) and magnetic resonance imaging (MRI) offer complementary strengths for this task, yet the validation of tracking algorithms against a reliable ground truth remains unresolved. Fluorescence microscopy can fulfill this role, but its integration into the highly constrained PET/MRI environment poses significant technical challenges. Here, we present a fluorescence microscope (FM) designed for simultaneous operation inside a small-animal PET/MRI scanner, with all custom structural and housing components 3D printed in polylactic acid (PLA). The assembled instrument has a total length of 95 cm and fits within the 35 mm PET insert bore, accommodating sample diameters of up to 21 mm. The imaging probe is rotated via a non-ferromagnetic, friction-driven mechanism, enabling multi-angle acquisition without repositioning the sample, and reliable rotation over the full 360° range was demonstrated under manual control. The system follows an epi-fluorescence configuration with 10× magnification, an excitation wavelength of 488 nm, and a 500 nm longpass filter in the detection path. Characterization with a calibration slide and a Convallaria majalis test specimen yielded a pixel pitch of 0.144 µm/pixel (6.96 pixels/µm), a spatial resolution of 2.32 µm (FWHM), a signal-to-noise ratio (SNR) of 7.21, and a field of view (FoV) of 0.55 × 0.31 mm2 (3816 × 2160 pixels), sufficient to resolve individual cells. These results establish the feasibility of integrating fluorescence microscopy into a PET/MRI scanner and provide the basis for future multimodal cell tracking studies with a reliable optical ground truth.

Abstract

Hadron therapy is a highly conformal cancer treatment technique that enables superior dose delivery to the tumor while sparing surrounding healthy tissues. However, its full clinical benefit is still limited by uncertainties in proton range within tissue, mainly due to the indirect estimation of ion stopping power from X-ray CT images. These uncertainties lead to safety margins that reduce treatment precision. Real-time, high-accuracy ion-range verification is essential to improve dose delivery and further enhance the therapeutic potential of proton therapy. Among the available approaches, PGI and PET are regarded as the most promising, as they provide complementary information. PGI offers direct correlation with the Bragg peak during irradiation, whereas PET yields high-resolution activity distributions from beta+ emitters produced along the proton path.

In this work, we report recent developments and experimental results obtained with a hybrid PGI-PET system for in situ proton range verification. The system is based on four high-efficiency two-plane Compton imagers arranged in a cross configuration, specifically optimized to enhance PGI sensitivity at the expense of a reduced PET field of view. Experimental campaigns were carried out at commercial IBA Proteus Plus and Proteus One proton therapy facilities using 100 and 125 MeV pencil beams delivered at minimum clinical currents. Polyethylene phantoms were irradiated at controlled positions and data were acquired during both in-spill and off-spill periods.

The first reconstructed 2D images demonstrate that PGI can directly identify the Bragg peak position through the maximum of the PGI distribution over a broad field of view, while PET provides a narrower and higher-resolution distribution associated with the induced beta+ activity. These results confirm the feasibility and complementarity of the hybrid PGI-PET approach and support its potential for accurate, clinically relevant proton range verification.

Intercrystal Compton Scattering Detection in Pixelated LYSO Detectors via Quantum Localization (#2993)

Amirreza Hashemi, Xi Zhang, Hamid Sabet

Harvard Medical School/Massachusetts General Hospital, Radiology Department, Boston, USA

This work was supported in part by NIH grant R01EB034785.

Abstract

We introduce a novel quantum-inspired method for identifying intercrystal Compton scattering in pixelated scintillation detectors. The approach treats each SiPM readout as a spatial signal and converts it into a discrete eigenfunction representation using a Hamiltonian built from the measured intensity distribution. Event structure is then assessed through quantum localization, quantified by the participation ratio. Single-site events produce highly localized dominant modes, whereas Compton-scattered events produce multiple localized modes associated with distinct interaction sites. A dual criterion based on quantum localization and eigenvalue proximity is used to classify multi-site events without calibration-intensive response modeling or supervised training. The method was evaluated with Geant4 optical photon simulations and measurements from LYSO:Ce detector arrays with thicknesses from 2 to 25 mm. Experimental classification agreed closely with simulation, with differences below 1% for most thicknesses and below 5% in all cases. These results indicate that the proposed representation captures the topology of gamma-ray interactions directly from detector signals.

Abstract

Positron emission tomography systems are becoming increasingly complex due to the growing number of detector channels and the large amount of data generated, especially in total-body imaging configurations. In this work, we present PETRARCA, a positron emission tomography detector system integrating an analog neural network ASIC (ANNA) for real-time edge computing of gamma-ray interaction coordinates within a monolithic scintillation crystal. The system consists of a 32 mm × 32 mm × 10 mm monolithic LYSO crystal coupled to an 8 × 8 SiPM matrix read out by dedicated front-end electronics. The detector architecture includes both a conventional digital acquisition path and a parallel analog inference path based on the ANNA ASIC, enabling simultaneous acquisition of sensor data and hardware neural-network predictions. A first evaluation of the system has been carried out using simulated data and the real ASIC response to emulate a reduced-scale configuration using a 4 × 4 SiPM array coupled to a 26 mm × 26 mm × 10 mm monolithic crystal. The performances of the ASIC in predicting the interaction coordinates were tested, and proved to have a mean absolute error (MAE) of around 1 mm on both the x and y axes. The preliminary results demonstrate the feasibility of analog neural-network edge computing for spatial localization in PET detectors and support further developments toward fully integrated real-time detector systems.

MIMOSA: Medical IMaging MOnte Carlo Simulation Algorithms for fast proton therapy range monitoring (#2751)

Declan D. Garvey, Gabriela Llosá, Fernando Hueso-González

IFIC, CSIC-UV, Valencia, Spain

This work has been funded by the Conselleria de Educación, Investigación, Cultura y Deporte (Generalitat Valenciana), Spain, under grant number CDEIGENT/2019/011, by CSIC's JAEPRE23-19 grant, and by the MIDAS project PID2022-143246OB-I00 (MICIU/AEI). IFIC is supported by the Severo Ochoa Center of Excellence grant CEX2023-001292-S funded by MCIU/AEI

Abstract

Monte Carlo simulations play a vital role in many aspects of proton therapy treatment, including proton depth of penetration monitoring. A key limiting factor of full simulation engines is computation time: simulations can take several days, far longer than the time between treatment fractions. This project aims to develop a Monte Carlo simulation software, MIMOSA, for prompt gamma-ray based proton range verification, that is fast enough to be deployed before the next treatment fraction. Clinically acceptable gamma pass rates above 99% for 2%/2 mm and 97% for 1%/1 mm with respect to TOPAS were achieved on both homogenous and heterogenous phantoms. To benchmark computational speed, state-of-the-art GPU codes MOQUI and FRED were tested on the same computer. Comparatively, MIMOSA achieved a notable speed increase, able to simulate 1e9 primary protons with a 200 MeV energy in approximately 3 minutes. Along with maintaining accuracy and increasing computational speed, the project uses the hardware agnostic SYCL standard, and will be available with an open-source license and extensive documentation. Ongoing work is devoted to simulating realistic radiotherapy treatment plans, and including prompt gamma-ray transport and detector response.

Analytical modeling and inclusion of object scatter in non-TOF 3D PET for low-count data (#1275)

Jorge Roser, Hong P. Vo, Magdalena Rafecas

Universität zu Lübeck, Institute of Medical Engineering, Lübeck, Germany

This work was supported by the European Union's Horizon 2024 research and innovation programme under the Marie Skłodowska-Curie grant agreement no. 101207067, and partly by the German Research Foundation (DFG) under grant agreement no. 508064995.

Abstract

Compton scattering in Positron Emission Tomography (PET) is commonly seen as an important degrading factor for the image quality. In particular, object scattering is known to reduce image contrast and distort quantification. Conventional scatter correction techniques do not model scatter directly in the system matrix, despite its potential to better handle low-count data scenarios. In this work, we propose an analytical model for single Compton scattering events and subsequently derive expressions of the system matrix and sensitivity. We validate the obtained expressions with Monte Carlo simulations. Ongoing work includes studying the impact of such approach by using low-count simulated data, and a comparison of the proposed method with conventional scatter correction techniques.

Validated Optical Simulation for High-Energy Gamma Response in a 3-Layer LYSO DOI Detector (#1668)

Shan Jiang, Giulio Lovatti, Francesco Evangelista, Peter Thirolf, Katia Parodi, Munetaka Nitta

Ludwig-Maximilians-Universität München, München, Germany

Abstract

We have developed a 3-layer staggered LYSO de tector with DOI capability within the project SIRMIO (Small animal proton irradiator for research in molecular image-guided radiation-oncology) for proton range verification via PET imag ing. To evaluate the feasibility of detecting prompt gamma rays for quasi-instantaneous monitoring of proton beams, we propose a workflow that includes the validation of optical simulation settings and the implementation of the saturation effect of the SiPM photonsensor in the Geant4 simulation. Measurement data with ^{152}Eu, ^{22}Na and ^{137}Cs radioactive sources are utilized for modeling the saturation effect of SiPM, and also for validating optical boundary settings in Geant4. The measured spectra of ^{22}Na and ^{137}Cs point sources are well reproduced with the proposed simulation workflow. The responses to prompt gamma rays are then simu lated. According to the floodmaps and profiles, LYSO pixel can be identified at 2.2, 4.4 and 6.2 MeV, but the contrast decreases strongly when energy reaches 6.2 MeV. The peak-to-valley ratios drop by up to 53% at 4.4 MeV and 62% at 6.2 MeV (relative to 2.2 MeV), primarily due to the energy deposition occurring more frequently in multiple LYSO pixels. These predictions suggest the detector’s potential for detecting prompt gamma rays, while accurately

recovering or rejecting inter-crystal scatter events is essential to maintain detector performance at higher gamma energy.

Identification of ICS Pixels in a high-resolution 3-Layer DOI-PET Detector Using a CNN (#2619)

Shan Jiang, Giulio Lovatti, Francesco Evangelist, Peter Thirolf, Katia Parodi, Munetaka Nitta

Ludwig-Maximilians-Universität München, München, Germany

Abstract

We have developed a 3-layer staggered LYSO DOI detector for the SIRMIO (Small animal proton irradiator for research in molecular image-guided radiation-oncology) project, with a crystal pitch of 1.0 mm. Due to the small crystal size, inter-crystal scatter (ICS) events degrade spatial resolution, while discarding them causes significant sensitivity loss. In our detector, ICS events account for approximately 50% of all interactions at 511 keV and result in a median lateral positioning error of approximately 2 mm. To solve this problem, we propose a dual-head convolutional neural network (CNN) for separating the 8×8 MPPC total response of two-pixel ICS events into two individual response matrices, from which the pixel positions and energy fractions can be obtained—a precondition for recovering the ICS events. The CNN correctly identifies both scattering pixels in 69.3% of test events, and in 26.4% of cases one pixel is correctly identified. Among the events with one pixel mismatched, the lateral error of the misidentified pixel falls within 1.0 mm in 91.0% of cases. Meanwhile, the median energy fractions prediction error is 0.016 per pixel. The results demonstrate that CNN-based MPPC response decomposition can serve as the enabling foundation for complete ICS recovery in 3-layer staggered DOI detectors, addressing a limitation explicitly acknowledged in recent physics-based ICS studies.

Abstract

MERMAID is the first PET scanner prototype dedicated to study small aquatic animals. Particularly, it aims to support the use of adult zebrafish as a model of human diseases. The current prototype, which consists of four detection modules composed of LYSO:Ce crystals, has demonstrated the capability of providing images with submillimeter resolution. An extension of MERMAID by another four modules is planned, aimed to increase the system sensitivity and allow for shorter scan times, making it more suitable for in-vivo imaging. In the presented work, various configurations for the extended MERMAID system are characterized by means of simulations and tailored reconstruction framework; modifications of imaging protocol for the system are investigated.

Abstract

Positron emission tomography (PET) requires dense detector crystals and associated electronics, resulting in high manufacturing costs. Sparse detector configurations can reduce hardware complexity but may degrade image quality due to reduced coincidence events, incomplete line-of-response coverage, and geometry-dependent artifacts. In this study, different sparse detector configurations were investigated for clinical PET imaging, and a sensitivity-informed network, termed SIU-Net, was proposed to recover image quality from sparse ring reconstructions. The residual sensitivity image was used as structural guidance to improve the restoration of degradation caused by detector sparsity. Experiments on 303 clinical brain datasets showed that the 1/2-TS-AR configuration achieved the best image quality among the evaluated sparse designs. SIU-Net consistently outperformed the baseline models across seven degraded image settings. These results demonstrate the potential of combining optimized sparse detector geometry with sensitivity-guided deep learning restoration for cost-effective PET imaging.

Anatomy-Guided Null-Space Learning for Self-Supervised Blind PET Deblurring (#2189)

Ziyuan Zhou, Ziwei Liu, Tzu-An Song, Fan Yang, Joyita Dutta

University of Massachusetts Amherst, Biomedical Engineering, Amherst, USA

Abstract

The intrinsically limited spatial resolution of positron emission tomography (PET) confounds image quantitation. Post-reconstruction deblurring is an ill-posed inverse problem in which the blur kernel is often unknown, and noise renders direct inversion infeasible. We present a principled framework for self-supervised blind PET image deblurring that incorporates high-resolution MRI anatomical guidance in a data-consistent way. The central contribution is an observation-dependent spectral decomposition of the PET image into a practical range space, i.e., the set of spatial frequencies recoverable from the blurry PET observation at a specified signal-to-noise ratio (SNR) threshold, and a complementary practical null space whose content cannot be estimated from the PET data alone, regardless of the estimator. A self-supervised deep learning framework, Anatomy-Guided Null-Space Learning (AGNS), instantiates this decomposition with three jointly optimized components: a blind 3D kernel estimation network, a range-space Wiener deconvolution, and an MRI-guided null-space imputation network. Joint optimization proceeds via the alternating direction method of multipliers (ADMM). Methodological evaluation is performed through clinical paired-resolution validation using images from the HRRT and NeuroEXPLORER (NX) scanners, where the NX images are only used as the validation ground-truth. AGNS produces strong qualitative and quantitative benchmarks relative to competing unsupervised and non-AI approaches.

Abstract

PET imaging enables quantitative assessment of disease burden and treatment response, but performance is constrained by a trade-off between radiation dose and image quality. Reducing injected adiotracer activity decreases patient exposure, yet increases image noise, degrading lesion detectability and quantitative accuracy. Total-body PET systems, with substantially increased sensitivity, enable significant dose reduction. However, ultra-low-dose acquisitions remain highly noisy, limiting their clinical utility. In this work, we investigate Brownian Bridge Diffusion Models (BBDM) as a novel framework for ultra-low-dose PET denoising. BBDM formulates dose-level image translation as a stochastic bridge between paired standard- and low-dose PET images, with the diffusion process constrained at both endpoints. This formulation is well-suited for dose translation. The proposed method was evaluated on a multi-center, multi-scanner total-body 18F-FDG PET/CT dataset of 80 patients. Paired full-dose and simulated 1/10-dose datasets were generated through statistical count reduction in the list-mode data. The model was trained with T = 1000 diffusion steps, and inference was accelerated using S = 200 sampling steps. On the held-out test cohort, BBDM achieved substantial gains across both global image-quality and lesion-level quantitative metrics. Compared with low-dose inputs, BBDM increased PSNR by approximately 26.6% and SSIM by 8.9%, while reducing RMSE by 60.0%. Across evaluated lesions, SUVmean and SUVmax biases decreased by 54.5% and 70.9%, respectively. Lesion noise was also reduced by 45.8%. The approach effectively preserves both image quality and lesion quantification at substantially reduced dose levels, highlighting its potential for ultra-low-dose total-body PET imaging.

Abstract

Low-dose or fast-scan single-photon emission computed tomography/computed tomography (SPECT/CT) suffers from Poisson noise, but clinical archives usually provide only one noisy standard-dose projection per patient and no noise-free target. A common single-scan workaround synthesizes a low-dose input from the standard-dose scan and uses the original projection as the supervised target. This creates a nested pair because the target contains the input photons, so the objective can learn a noisy full-dose image with input-noise leakage. We propose a self-supervised projection-domain framework based on mutually exclusive Poisson thinning. Each standard-dose projection is partitioned online into $K \in \{2,3,4,5\}$ disjoint equal-dose subsets by multinomial assignment, and two subsets are randomly paired for Noise2Noise training. These paired subsets contain disjoint photons and are conditionally independent given the underlying count rate while preserving the same dose; mean-square or Poisson-likelihood training therefore targets the clean same-dose conditional mean rather than a noisy full-dose target. A three-dimensional residual U-Net is trained only from thinned noisy pairs and applied before OSEM reconstruction. Training used 225 clinical bone SPECT/CT cases. On 31 held-out cases evaluated by patient-specific controlled Poisson resampling over 1×--5× fast-scan factors, the method achieved 45.72 dB PSNR and 0.9862 SSIM in the projection domain, outperforming an architecture-matched low-to-standard-dose supervised baseline by 2.68 dB; the paired gain increased from 1.82 dB at 1× to 3.34 dB at 5×. The framework enables low-dose bone SPECT/CT denoising from routinely stored projections without clean ground truth or repeated acquisitions.

Abstract

Accurate attenuation and scatter correction is important for positron emission tomography (PET) to improve diagnosis. Conventional PET correction pipelines rely heavily on CT-derived attenuation information, which inevitably increases radiation exposure during clinical examinations, especially in total-body PET/CT imaging. In this study, we introduce a vision-language-model-guided conditional flow framework for CT-free PET attenuation and scatter correction. Specifically, non-corrected PET slices are analyzed to generate organ-aware textual prompts, which are subsequently encoded as semantic representations and integrated into a latent-space flow generation process. Then, a cross-modal attention mechanism is further designed to establish interactions between semantic prompts and PET image features under multiple scales during conditional flow matching. Experiments were performed on 264 clinical subjects under total-body PET/CT scans. Comparison methods consist of several representative deep learning approaches, including UNet, Uformer, CycleGAN, latent diffusion models, and VM-UNet. Quantitative evaluation demonstrated that the proposed framework achieved the highest metric index, reaching 38.66 dB PSNR and 0.9754 SSIM on the testing dataset. Visual assessment and Correlation Analysis additionally confirmed improved anatomical continuity and more accurate tracer uptake recovery. The study suggests that semantic-aware flow modeling offers an effective strategy for CT-free PET correction.

Implicit Neural Representations for Joint Motion-Resolved PET Reconstruction and Respiratory Gating (#3089)

Nicolas De Bie, Massimiliano Colarieti Tosti

KTH Royal Institute of Technology, Department of Biomedical Engineering and Health Systems, Stockholm, Sweden

Abstract

Respiratory motion during acquisition degrades image quality in positron emission tomography (PET). Data-driven gating (DDG) extracts a respiratory signal directly from the measurement data, but classical methods such as axial center-of-mass and principal component analysis (PCA) degrade under irregular breathing and at low count rates. We propose a self-supervised framework based on implicit neural representations (INRs) that jointly estimates a respiratory gating signal and a motion-corrected reconstruction. Two coordinate-based networks parametrize a motion-free canonical activity image and a deformation field conditioned on learnable per-frame latent codes that encode the respiratory state. We evaluate the framework on XCAT thoracic phantom simulations of an 18F-FDG acquisition at clinically realistic count levels under regular and irregular breathing. The recovered gating signal achieves Spearman correlations of 0.87 (regular) and 0.85 (irregular) with the ground-truth respiratory signal, exceeding center-of-mass (0.62; 0.30) and PCA-based (0.74; 0.34) DDG baselines, and the framework simultaneously produces a motion-resolved reconstruction with PSNR comparable to maximum likelihood expectation maximization (MLEM) reconstruction.

Abstract

Long axial field-of-view (LAFOV) PET enables imaging at very late timepoints but requires repeated CT acquisitions for attenuation correction (AC) in multi-time-point protocols, increasing radiation exposure. This study evaluates two CT-free AC strategies for [^{18}F]PSMA-1007 LAFOV PET at delayed imaging timepoints: synthetic μ-maps derived from non-attenuation-corrected PET imaging using a ResNet-based model (Synth-AC) and elastic co-registration of CT-based μ-maps from the initial scan (CoReg-AC). Ten patients were scanned on a Siemens Biograph Vision Quadra LAFOV system at 90 min, 3 h, and 5 h p.i. Quantitative evaluation was performed based on relative differences in SUV_{mean} across seven major organs. Lesion quantification was assessed for SUV_{mean} (28 lesions at 3 h p.i., 20 lesions at 5 h p.i.) using Bland–Altman analysis and linear regression. Visually, synthetic μ-maps appeared smoother, while co-registration preserved more anatomical detail but showed localized inconsistencies. In PET images, Synth-AC exhibited smaller and more homogeneous deviations (±5%), whereas CoReg-AC showed more pronounced peripheral differences. At organ level, reduced variability was observed at 5 h for both methods. CoReg-AC showed a positive bias in high-uptake organs (liver +1.7% to +4.3%, spleen +2.7% to +4.3%), while Synth-AC shifted from near agreement at 3 h to moderate negative bias at 5 h (liver −2.1%, heart −13.5%). Both methods demonstrated a pronounced positive bias in lung regions. Linear regression demonstrated strong agreement with CT-based AC (R^2 = 0.993–0.998), and Bland–Altman analysis at 3 h p.i. showed a mean bias of −0.97% with limits of agreement [−12.11%; +10.17%] for Synth-AC and +1.40% [−8.71%; +11.52%] for CoReg-AC. Both CT-free approaches enable robust quantitative imaging in delayed LAFOV PET. Observed differences are primarily driven by organ-level bias patterns, while lesion quantification remains stable.

3D Latent Implicit Diffusion for Scalable Volume Generation (#2875)

Youness Mellak, Alexandre Bousse, Antoine De Paepe, Dimitris Visvikis

Université de Bretagne Occidentale, LaTIM, INSERM, UMR 1101, Brest, France

Abstract

Full-volume 3-D medical image generation at clinical resolutions remains a significant challenge due to GPU memory constraints. Direct voxel-space generative modeling becomes increasingly difficult once spatial resolution exceeds 256^3, especially on single-GPU hardware. Latent diffusion approaches reduce this burden by performing generation in a compact representation [1], but decoding onto a dense fixed grid remains costly at high resolution. Implicit neural representations offer an attractive alternative, as they reconstruct images by querying continuous spatial coordinates rather than materializing a full voxel grid [2], making them naturally suited to memory-efficient volumetric generation.

We propose a memory-efficient 3-D latent implicit diffusion framework that combines a lightweight 3-D encoder with a coordinate-conditioned local implicit decoder, inspired by [3]. The encoder compresses the input volume into a compact latent grid, while the implicit decoder reconstructs the volume by querying continuous spatial coordinates from learned latent features, avoiding the need to materialize the full voxel grid during training. A full-volume 3-D diffusion model is then trained directly in this compact latent space. At inference, new volumes are generated by sampling from the diffusion model and rendering the full grid through the implicit decoder.

We validate our framework on CT and MRI volumes at resolutions up to 512^3 on a single consumer-grade GPU, demonstrating coherent full-volume generation across axial, coronal, and sagittal planes without materializing the full voxel grid at any stage of training.

Abstract

The coincidence time resolution of scintillation detectors plays a critical role in time-of-flight positron emission tomography (TOF-PET) and it is fundamentally limited by the emission, transport, and detection processes of scintillation photons. Although previous analytical and Monte Carlo simulation studies have suggested that exploiting multiple timing information of scintillation photons could approach the theoretical timing limits, direct experimental access to all detected photon timestamps remains unavailable with standard PET detectors using analog silicon photomultipliers (SiPMs). To address this challenge, we previously proposed a deep learning-based approach to recover photon timestamps on an event-by-event basis by removing the SiPM degradation factor from detector waveforms within an unsupervised learning framework. Our experimental evaluations demonstrated that the recovered photon behavior is consistent with previous findings, although the absence of ground-truth timestamps inevitably limited a rigorous and quantitative assessment of its validity and reliability. In this study, we evaluate the proposed method using Monte Carlo simulation data with fully known photon-level information. The recovered photon timestamps were quantitatively compared with the true timestamps in terms of timing bias, timing uncertainty, and total photon count fidelity. The results showed that the proposed method achieves timing biases within approximately 10 ps and maintains acceptable timing precision across photons while accurately preserving the number of detected photons per event. With the optimized parameter settings, we will further improve temporal precision in timestamp recovery using experimental data.

Abstract

In positron emission tomography (PET), inter-crystal scattering (ICS) is a major source of uncertainty contributing to spatial resolution. While rejecting ICS events can improve the resolution, it comes at the cost of sensitivity. Accurately recovering the first interaction position is therefore crucial for maintaining both high sensitivity and spatial resolution.

In this work, we apply ICS recovery to experimental data from semi-monolithic detectors, with a 2:1 slab-to-SiPM ratio using both analytical and deep-learning (DL) approaches. We developed a GATE Monte Carlo simulation framework tuned to reproduce experimental signals for data augmentation. A multilayer perceptron (MLP) achieved ~78% exact layer prediction, with an additional ~15% misassigned by only one slab, leaving just ~7% exceeding 1.5 mm (one slab thickness). This outperforms analytical methods, particularly for ICS-only events, where the MLP is 16 percentage points more accurate, and the analytical method fails entirely at edge slabs. We show simulated signals closely match experimental data; additional tuning will enable their use in training networks for experimental application.

This study takes a first step toward combining simulated and experimental data for DL-based ICS recovery, which could bypass individual detector array calibration.

Abstract

High-resolution SPECT imaging requires detectors with high intrinsic spatial resolution, good energy resolution, and high detection efficiency. Pixelated scintillator arrays are commonly used to improve the intrinsic spatial resolution, but sub-millimeter pixels increase fabrication complexity and cost, and inter-crystal gaps may reduce detection efficiency.

In this work, we developed and evaluated a semi-monolithic GAGG SPECT detector composed of 29 stacked continuous crystal slabs. Each slab measured 25.8 × 0.8 × 6 mm³, and adjacent slabs were separated by 0.08 mm-thick $BaSO_4$ reflectors. The detector was coupled to a silicon photomultiplier (SiPM) array (Hamamatsu MPPC S14161-3050HS) and read out using a PETsys TOFPET2 ASIC. A tungsten parallel-slit collimator with 13 slits, a 2 mm pitch, and a 0.8 mm slit width was placed directly in front of the detector entrance surface for flood image, energy resolution (ER), and intrinsic spatial resolution (ISR) measurements.

Most pseudo-pixels (defined as discrete areas on the flood image based on the crystal look-up table) were clearly resolved in the flood image, except for several edge crystal pixels, with average peak-to-valley ratios of 5.4 ± 2.1 and 7.4 ± 3.9 in the X and Y directions, respectively. Within a 110–170 keV energy window, DOI-based energy correction improved the average ER from 15.37% ± 1.75% to 11.07% ± 0.77% at 140 keV. The average ISR were 1.02 ± 0.36 mm and 0.42 ± 0.29 mm in the X and Y directions, respectively.

In conclusion, these results demonstrate that the proposed semi-monolithic GAGG detector can achieve good energy resolution and sub-millimeter-level intrinsic spatial resolution, showing potential for high-resolution SPECT imaging.

Abstract

Recent applications of Positron Emission Tomography (PET) in dosimetry such as Pair Production Tomography (P2T) or Proton Range Verification (PRV) require a detector count rate capacity far beyond the conventional range for diagnostic-oriented PET. Most commonly used PET detectors use scintillation crystal coupled to silicon photomultipliers (SiPMs). For high count rate situations the scintillation decay time in the range of tens of nanoseconds can lead to undesired pile-up effects.

In this work, we explore the feasibility of using Cherenkov-only emitter based on PbF_2 coupled to SiPMs to overcome the limitation posed by the long scintillation tails. While Cherenkov-only emitters have been proposed and tested for ultra-fast timing in time-of-flight PET (TOF-PET), the goal of this work is to evaluate the feasibility of using them in readily scalable setup.

We used 3×3×3-20 mm^3 PbF_2 crystals coupled to Broadcom NUV-MT SiPMs (4×4 mm^2) and custom low-noise high-frequency (LN-HF) readout electronics. SiPM over-voltages from +2 to +8 V and different trigger levels were evaluated to determine the optimal performance for this type of application, focusing on the true coincidence fraction (TCF), coincidence ratio and coincidence timing resolution (CTR), in order to assess if the Cherenkov signals are discernible from background noise. Additionally, we tested the same setup read out by an ASIC (FastIC evaluation board) to understand the impact of an integrated system-applicable readout. Using LN-HF-readout electronics and an excess bias voltage of +4 V we measure a TCF of 81% and a CTR of 240±2 ps. Using the FastIC ASIC, the best results were a TCF of 81% and a CTR of 506±6 ps. Our results demonstrate the potential of Cherenkov-only radiators for high count rate PET applications.

Abstract

A prototype stationary tomographic ultra-fast Molecular Breast Imaging system (UFMBI) has been developed and characterised using phantom studies. The system combines ultra-high resolution CZT detectors with depth-of-interaction (DOI) sensitivity and wide-angle sampling from densely packed multi-pinhole (MPH) collimators, together with novel de-multiplexing reconstruction to mitigate multiplexing artefacts. This approach enables substantial reductions in scan time (~40 min) and radiation dose (~2.4 mSv) compared with conventional MBI, supporting wider adoption as a supplemental screening tool for women with dense breast tissue.

A dual-head prototype with a field-of-view of 132mm x 88mm has been designed and built. Each head consists of a 6x4 array of 5 mm thick CZT detectors with 11x11 grid of 2 mm pixels. Raw detector data are processed using a machine learning model providing 10x10 sub-pixelisation and DOI sensitivity. Image reconstruction uses OSEM algorithm incorporating attenuation, collimator blurring, septal penetration and multiplexing effects.

Performance was evaluated using uniform and spherical lesion phantoms (5–9 mm) at tumour-to-background ratios of 10–20:1, with comparison to a clinical planar MBI system by imaging ^{99m}Tc-infused gel phantoms. Dose/time reduction factors (DRF) were evaluated by resampling measured data relative to the reference equivalent to current clinical practice. Lesion detectability was assessed using contrast-to-noise ratio (CNR) and the Rose criterion (CNR>3). Sphere studies demonstrated detectability of 5–7 mm lesions at DRF = 8. Gel phantom experiments showed that UFMBI achieved ~2.9× higher CNR than the clinical system at reference conditions and ~2× higher at DRF = 6.

These results demonstrate the feasibility of UFMBI as a high-throughput tomographic extension of conventional MBI, with potential application as a supplemental screening tool for women with dense breasts.

Abstract

The ultrafast nature of Cherenkov photon emission offers an avenue to improve the coincidence time resolution (CTR) of time-of-flight positron emission tomography (TOF-PET) detectors. Bismuth germanate (BGO) provides a higher Cherenkov photon yield than conventional lutetium-based crystals, but its slow scintillation component induces large variations in signal shape. Measuring the rise time of the signals, obtained from the time difference between two threshold crossings, enables classification of events by Cherenkov yield and time-offset correction to improve the CTR. While this principle has been demonstrated with dedicated fast electronics, scalable implementation remains a challenge. Here, we exploit the dual-threshold capability of the new FastIC+ ASIC to extract rise-time information in BGO-based detectors and study the influence of bias voltage, settings of thresholds, and rise-time correction methods on CTR performance. We obtained a 32% CTR improvement, from 577 to 395 ps FWHM, with 3×3×15 mm^3 polished BGO coupled to 3×3 mm^2 FBK NUV-MT SiPMs biased at 49 V, and we show trade-offs between noise rejection and rise-time correction efficiency as a function of the two selected thresholds. This work marks a concrete step toward a scalable approach to exploiting BGO's mixed Cherenkov–scintillation emission in TOF-PET imaging.

Abstract

Simultaneous PET and SPECT imaging enables concurrent characterization of multiple biological processes, but conventional multi-modality systems typically require separate detector subsystems. We previously proposed a scintillator-as-collimator design for a PET&SPECT shared detector, and demonstrated PET, SPECT, and simultaneous PET&SPECT imaging capabilities. Nevertheless, the scintillator-as-collimator volume (SCV) lacked depth-of-interaction (DOI) discrimination in PET mode, and the thickness of the SPECT Detector volume (SD) was not optimized, compromising its time-of-flight (TOF) PET performance. To address these limitations, we developed an optimized two-layer PET&SPECT detector with a top 16×16 LYSO array (1.53×1.53×10 mm³) and a bottom 8×8 LYSO array (3×3×10 mm³), separated by two 2-mm light guides. The block was coupled to an MPPC array and read out by a PETsys TOFPET2 ASIC. To evaluate the effect of hole drilling on performance, two prototype detectors were fabricated: a drilled detector with holes in the top LYSO array and light guides, and a non-drilled reference. Both detectors used unpolished crystal sides with $BaSO_4$ reflectors. Flood images, energy resolution (ER), DOI resolution, and coincidence time resolution (CTR) were evaluated.

The drilled detector achieved effective DOI discrimination in both SCV and SD. After excluding ICS events, DOI resolutions of 3.60 ± 0.43 mm and 2.18 ± 0.15 mm were obtained in the top and bottom layers, with a bottom-to-bottom CTR of 259 ps. The DOI and CTR are comparable to those of the non-drilled reference detector.

In conclusion, these results validate the optimized two-layer scintillator-as-collimator design and demonstrate its potential for a PET&SPECT shared detector with high DOI and TOF performance. Future work will evaluate the capability of the SD region in detecting 140 keV gamma photons and develop a prototype system for imaging validation.

Abstract
Time-of-Flight Positron Emission Tomography requires readout electronics capable of extracting precise timing information. The Positron Emission Tomography Integrated Circuit (PoETIC) has been developed to bridge the performance gap between the intrinsic timing resolution of the detector and that achievable with integrated readout solutions, while remaining scalable in channel count and power consumption. PoETIC introduces a novel channel architecture based on two fully independent analog front-ends per channel, separately optimized for timing and energy measurements, and thereby relaxing conflicting design requirements at the input stage. Fabricated in 65 nm CMOS technology, the PoETIC die integrates fast low-noise front ends, dual-threshold discriminators and a TDC with 24.4 ps time binning. Four 16-channel dies are combined into a 64-channel 2.5D Integrated Circuit. A custom high-speed serial interface supports daisy-chained data and trigger distribution, significantly reducing interconnect complexity. The power consumption is 10 mW per channel. Measurements of a first prototype show a single-photon time resolution of 57 ± 1 ps FWHM and 85 ± 1 ps FWHM using FBK NUV-HD-MT SiPMs of 1×1 mm² and 3×3 mm², respectively. Preliminary measurements yield a coincidence time resolution of 74 ± 1 ps FWHM with the

3×3 mm² SiPMs and LGSO crystals of 2×2×3 mm³. To the best of our knowledge, these results represent state-of-the-art timing performance for an ASIC and suggest that PoETIC approaches the intrinsic timing performance of scintillator crystals while offering a flexible and scalable readout solution for next-generation PET systems and other fast-timing applications.

Detection efficiency of a lead-loaded plastic scintillator for positron emission tomography detectors : A Monte Carlo study (#1086)

Makoto Yamazaki[1], Masahiro Sato[2]

[1] Gunma Prefectural College of Health Sciences, Department of Radiological Technology, School of Radiological Technology, Gunma, Japan; [2] Shinshu University, Graduate School of Medicine, Science and Technology, Nagano, Japan

This study was supported by the individual research fund and overseas travel grant of Gunma Prefectural College of Health Sciences.

Abstract

Lead-loaded plastic scintillators are promising candidates for next-generation positron emission tomography (PET) detectors, combining the fast timing response and low cost of organic scintillators with enhanced gamma-ray stopping power due to heavy-element doping. This study evaluates the 511-keV photon detection performance of EJ-256, a commercially available plastic scintillator containing 5 wt% lead, relative to a conventional polyvinyltoluene (PVT) scintillator using Monte Carlo simulations. All simulations were performed in Geant4 (v11.1.1). Monoenergetic 511-keV gamma rays were incident on scintillator blocks with a fixed cross-section of 4 × 4 mm² and thicknesses ranging from 20 to 200 mm in 5-mm increments. For each configuration, 100,000 primary events were simulated, and the resulting energy-deposition spectra were analyzed in ROOT. Detection efficiency was defined as the fraction of incident photons depositing 505–515 keV within the scintillator volume. EJ-256 exhibited a distinct fullenergy peak at 511 keV, whereas the reference PVT scintillator showed only a broad Compton continuum. Detection efficiency for EJ-256 increased from 0.9% at 20-mm thickness to 2.9% at 200 mm, consistent with enhanced photon absorption at greater thicknesses. However, efficiency gains became marginal beyond approximately 135 mm, indicating practical saturation. The energy resolution remained approximately constant at ~10% full width at half maximum across the investigated thickness range. These results indicate that moderate lead loading enhances 511-keV photon detection in plastic scintillators without compromising spectral stability, supporting the potential of EJ-256 as a cost-effective candidate for PET detector modules.

Exploring CTR improvement through structural refinement of orthogonally stacked PET detector (#1253)

Arisa Sanzen, Yuya Onishi, Ryosuke Ota

Hamamatsu Photonics K.K., Central Research Laboratory, Hamamatsu, Japan

Abstract

Time of flight positron emission tomography (TOF-PET) plays an important role in the diagnosis of Alzheimer's disease and cancer because it enables localized estimation of lesion positions. Improving coincidence time resolution (CTR) is essential for enhancing the precision of lesion position estimation. Currently, commercially available PET systems achieve a CTR of approximately 200 ps full width at half maximum(FWHM), while the next goal is to reach 100 ps FWHM at the system level. However, commercial PET systems employ thick scintillators for high detection efficiency, resulting in a trade-off between CTR and detection efficiency due to photon transport time spread. To overcome this trade-off, we proposed xDetector, a readout scheme in which detector groups are orthogonally stacked. xDetector employs shorter scintillators than conventional detectors to improve CTR, while maintaining detection efficiency through multiple layers stacked. In addition, by orthogonally stacking detector groups via air coupling, it is possible to estimate the interaction position within the scintillator, which contributes to further CTR improvement. In previous study scintillator crystals and multi pixel photon counters (MPPC)s with 4.2 mm pitch were optimized for CTR measurements together with a high-frequency readout circuit. However, it was demonstrated that the CTR of xDetector with 3.2 mm pitch was 10% faster than that with 4.2 mm pitch, which can be attributed to faster time response of 3 mm MPPC than 4 mm. Thus, in this study, we aimed to further improve CTR by leveraging geometric flexibility and adopting small crystals with the same cross-sectional pitch of MPPCs compared to previous configurations. Through this investigation, we explore the potential of xDetector towards realizing 100 ps CTR.

Abstract

Depth-of-interaction (DOI) estimation can reduce parallax error in PET imaging, but conventional pixelated detectors usually require additional DOI-encoding hardware or modified detector geometries. This study investigates a cost-effective neural network approach to recover DOI information from a state-of-the-art air-coupled pixelated PET detector using only compact engineered features, which could be extracted directly by front-end ASICs without digitizing all silicon photomultiplier (SiPM) channels. A Geant4 optical simulation was performed, and neural networks were trained for both 3D position regression and DOI-bin classification. The feature-only model achieved DOI performance comparable to models using the full raw SiPM counts, with an MAE_z of 1.107±0.001 mm, and an F1 score of 0.790 for DOI-bin classification, with most classification errors occurring between neighboring bins. These results demonstrate a practical and cost-effective pathway to enable DOI capability without changing the detector geometry, while reducing readout complexity, system cost and power consumption.

Abstract

Photon-counting computed tomography (PCCT) has attracted attention because of its potential for high spatial resolution, low-dose imaging. Although semiconductor detectors are widely studied for PCCT, indirect-conversion detectors with fast and bright scintillators combined with silicon-photomultipliers arrays (SiPMs) have recently emerged as promising alternatives owing to their potential for the scalability and cost effectiveness. Though $Gd_3(Al,Ga)_5O_{12}$ or $(Lu,Y)_2SiO_5$ shows an excellent scintillation properties, Kα escape peak of Gd (43 keV), and Lu (55 keV) degrade the accurate photon counting. Instead, Mg co-doped $Y_3(Al,Ga)_5O_{12}$:Ce (YAGG) garnet scintillators with lower Kα escape peak (<15 keV) is developed for X-ray imaging applications. The effect of Mg co-doping on scintillation properties results in representing 5-7 folds increase in the light yield of 35,000 photons/MeV@662 keV and the decay time of <50 ns. In addition, synchrotron X-ray imaging performance demonstrates that the spatial resolution of Mg co-doped $Y_3Al_3Ga_2O_{12}$:Ce is comparable to that of LuAG:Ce with the 1 mm sample thickness. Although the density of YAGG:Ce,Mg (5.08–5.33 g/cm) is lower than that of LuAG:Ce (6.67 g/cm), there is a concern regarding X-ray stopping power and deterioration of spatial resolution, the linear attenuation coefficients at 12.4 keV are sufficiently high (273–350 cm^{-1} for YAGG:Ce,Mg and 943 cm^{-1} for LuAG:Ce), resulting in X-ray absorption efficiencies exceeding 99.99% for 1 mm thickness samples, indicating negligible influence on imaging performance in the lower energy range. Moreover, we also demonstrate the feasibility of YAGG:Ce,Mg to medical field from the success in clear imaging of small, dried fish. These results show that YAGG:Ce,Mg scintillators are promising candidates for next-generation X-ray imaging detectors and can be applied for indirect-conversion PCCT applications.

Optimal Radiator Refractive Index for Cherenkov-Radiator-Integrated PET Detectors: A Simulation Study (#1942)

Taiyo Ishikawa[1,2], Ryosuke Ota[3,4], Hideaki Haneishi[5], Taiga Yamaya[2,5]

[1] Chiba University, Graduate School of Science and Engineering, Chiba, Japan; [2] National Institutes for Quantum Science and Technology, Institute for Quantum Medical Science, Chiba, Japan; [3] Hamamatsu Photonics K.K., Central Research Laboratory, Hamamatsu, Japan; [4] University of California, Davis, Department of Biomedical Engineering, Davis, USA; [5] Chiba University, Center for Frontier Medical Engineering, Chiba, Japan

Abstract

In positron emission tomography, time-of-flight information can localize source positions along lines of response. Cherenkov-radiator-integrated microchannel-plate photomultiplier tubes (CRI-MCP-PMTs) with a 3.2-mm-thick lead glass window (n~1.5) have achieved 30-ps coincidence time resolution (CTR). However, improving coincidence detection efficiency remains a challenge, as increasing the radiator thickness degrades the CTR. In this study, we focused on the radiator refractive index. Based on the Frank-Tamm formula, we hypothesized that ultraviolet-transparent materials with a high refractive index would increase Cherenkov photon production, reducing event loss. Furthermore, increased Cherenkov photon detection would improve effective single-photon time resolution, thus enhancing CTR. We tested this hypothesis using Geant4 simulations of point-source measurements with paired CRI-MCP-PMTs incorporating optical and detector characteristics. Assuming wavelength-independent refractive indices from 1.7 to 3.0, we found coincidence detection efficiency increased from 1.1% to 3.0% whereas CTR deteriorated from 41.5 to 49.6 ps. Contrary to our expectations, the reduced speed of light in the medium increased timing jitter, overriding the CTR benefits from detecting more Cherenkov photons. A similar simulation for lead fluoride radiators (n~1.7–2.1)—expected to improve efficiency while maintaining the CTR—showed a worse CTR (46.4 ps) was obtained than for the wavelength-independent cases (~42.0 ps). Wavelength-resolved analysis showed a CTR of 53.3 ps for 240–340 nm photons, which was unexpectedly worse than that of 39.9 ps for 540–640 nm photons, despite the higher theoretical photon production in the shorter band. One possible cause is the steep refractive index dispersion in the shorter band. In summary, while higher refractive indices improve coincidence detection efficiency, they can degrade CTR. Minimizing refractive index dispersion is critical for fast timing.

Fabrication of diamond detectors with graphitic contacts for tissue equivalent dosimetry (#2040)

Ivan Lopez Paz, **Ivan Lopez Paz**, Consuelo Guardiola, Consuelo Guardiola, Gemma Rius, Gemma Rius

Institut de Microelectronica de Barcelona (IMB-CNM, CSIC), Bellaterra, Spain

This work has been funded by the IMB-CNM (CSIC) TRIGGER projects PIACeD and CarDos4FLASH, supported by the 'María de Maeztu Unit of Excellence' accreditation (CEX2023-001397-M / AEI/10.13039/501100011033). This study was also funded RYC2024-050777-I project, financed by the MICIU / AEI / 10.13039/501100011033 and FSE+.

Abstract

Diamond-based dosimeters are popular for medical dosimetry in view of their fast response, radiation hardness and tissue equivalence. However, some design improvements to achieve better accuracy in signal readout and approach tissue equivalence are possible by the removal of the metallic contacts, sometimes covering the active area of said devices.

In this contribution, we explore the use of a simple processing and scalable solution to obtain non-metal, low Z electrical contact. Thus, the fabrication of diamond detectors with graphitic contacts at the Microelectronics Institute of Barcelona are shown. Several approaches are explored, some of which never utilised before for radiation detector fabrication, namely pyrolytic photoresist film, nickel catalysis and ion surface graphitisation.

A prototype of such device using the pyrolytic photoresist film process for the first time has been produced and was tested under a 60 kV X-ray tube. We report the fabrication and preliminary performance results of such device. Although the substrate material quality is not ideal for radiation detection, it was possible to observe radiation response using the PPF as an interface material. The prototype features a linearity better than 3% as tested in a laboratory X-ray chamber, proving it a promising technology for detector operation. Finally, the technology challenges are finally discussed to assess the feasibility of PPF-diamond technology for dosimeter batch production.

Abstract

Accurate localization of annihilation γ-ray interaction positions within detector block is essential for achieving high spatial resolution in positron emission tomography (PET). Conventional high-resolution PET detectors often use finely pixelated scintillator arrays resulting in increased system cost due to the larger number of crystal elements and number of readout-channels. Semi-monolithic scintillator detectors offer an alternative solution by enabling signal-based position estimation with reduced readout. In this work, we experimentally evaluated a classification-based multilayer perceptron (class-MLP) for estimating the γ-photons interaction position direction within each semi-monolithic LYSO detector slab across a cassette of 40 mini-modules (mM), each comprised of 16 LYSO slabs coupled to 8x8 SiPMs and read by 16 readout channels, developed for the Ultra-High-Performance Brain PET (UHB-PET) system. Calibration data were acquired from each of the 40 mM, and operated on a benchtop setup using a 0.5mm slit-collimated source translated in 0.5mm steps. The class-MLP used 24 multiplexed readout and classified events into 49 position bins spanning 0-24mm along the monolithic. Independent MLPs were trained for the individual mM. After correction for the finite collimator resolution, the mean positioning-error FWHM was 1.29±0.13mm (range: 0.85 to 1.41mm). The corresponding FWTM was 3.91±0.29mm (range: 3.29 to 4.73mm). Our results demonstrate that class-MLP can achieve near-millimeter detector mean spatial resolution along the monolithic dimension in 20mm-thick semi-monolithic LYSO detectors with minimal variability across all mM of a UHB-PET cassette. Future work will focus on acquiring calibration data from all cassettes in the fully assembled UHB-PET scanner to characterize its system-wide detector spatial resolution using the current calibration strategy per mM.

Abstract
Laser engraving of monolithic scintillators to create pixel boundaries has been around already for some time, with the promise of good pixel identification as in conventional pixelated detectors, but at a much lower cost. However, their use is hindered by the fact that the pixel boundaries are semi-transparent, making it difficult to identify the pixel of interaction with the algorithms applied to fully pixelated detectors. The RETIMAGER project proposes laser-engraved (LE) pixelated LYSO blocks, with optimized transparency of pixel boundaries that might be exploited to obtain depth-of-interaction (DOI) based on the light spread in the SiPM array, while keeping crystal pixel identification. Hexagonal SiPM arrays, scintillators and pixel cells are introduced, improving packing fraction and reducing gaps in between detectors, but adding difficulty when applying ordinary vertex identification strategies. We present the experimental DOI performance for several RETIMAGER detectors, engraved with different optical densities (and thus trasparencies) por hexagons of 1.25 mm side. Data is acquired in a testbench with a collimated source, and employed to train an NN algorithm, to predict DOI. For a 13 mm thick crystal, DOI assignation uncertainty ranges from 2.4 to 3.2 mm FWHM, depending on the trasparency of the boundaries, with the highest trasparency detectors exhibiting the best results. Experimental results follow the trend of the simulations, which can be used to further optimize the DOI performance and to reduce bias.

Abstract

Bismuth germanate (BGO) is a high-density and cost-effective scintillator for PET detectors, but depth-of-interaction (DOI) encoding with single-ended readout remains challenging due to its relatively low light yield. This study investigated a light-sharing based BGO detector using paired crystals for DOI encoding. The effects of reflector geometry and lateral surface treatment were evaluated to optimize detector performance. Among the unpolished configurations, the trapezoidal reflector provided the best DOI encoding capability, achieving an average DOI resolution of 5.29 mm FWHM and an energy resolution of 20.4%. Partial surface polishing improved energy and timing performance but degraded DOI encoding capability. After applying timing correction based on DOI and rise-time correction, the timing resolution of the unpolished trapezoidal configuration improved from 427 ps to 353 ps FWHM. These results suggest the feasibility of a single-ended DOI approach for BGO PET detectors with potential time-of-flight (TOF) applications.

Abstract

Time-of-flight (TOF) positron emission tomography (PET) performance is governed by the coincidence time resolution (CTR), which is fundamentally constrained by the number and arrival-time distribution of scintillation photons reaching the photosensor. To enhance both quantities, we fabricated nano-scale line- and hole-type photonic crystal (PhC) patterns with a 1.2 μm period on the polished 3×3×20 mm³ surfaces of lutetium-yttrium oxyorthosilicate (LYSO) scintillators via flex-mold soft lithography using a UV-curable optical resin (n = 1.5). Six SiPM coupling conditions were evaluated: bare LYSO with and without grease, and line- and hole-type PhC patterns each with and without grease.

The intrinsic scintillation photon arrival-time distribution was reconstructed by deconvolving each measured waveform with the single-photoelectron (SPE) response of a photomultiplier tube (PMT), and the absolute light gain of each PhC geometry was independently assessed in an airgap PMT configuration by comparing the photopeak before and after patterning. PhC-patterned crystals achieved a 42.8% reduction in deconvolved rise time and light gains of 1.20 (line) and 1.18 (hole). To quantify the redistribution of photon arrivals, fractional yields were computed within three time windows — early (0–1 ns), mid (1–10 ns), and late (10–50 ns) — normalized to the total yield over 0–50 ns. The early-window yield increased from 0.7% to 0.9% (a 33.5% relative gain), the mid-window yield rose from 19.8% to 21.2%, and the late-window yield decreased from 79.5% to 77.9%, confirming a redistribution of photon arrivals toward the earlier windows.

In SiPM CTR measurements, the line-type PhC combined with grease achieved the best CTR of 180.6 ps, a 29.5% improvement over the bare crystal. These findings demonstrate that nano-scale PhC patterning improves CTR in LYSO-based TOF-PET by enhancing both the absolute light yield and the prompt photon density.

Abstract

X-ray fluorescence imaging (XFI) is an emerging molecular imaging technique that combines high sensitivity with high spatial resolution, offering significant penetration depth in tissues while minimizing ionizing radiation exposure compared to other existing methods. This makes XFI a promising tool for tumor characterization and personalized treatment. The IMMPRINT project aims to develop a proof-of-principle demonstrator that leverages X-ray fluorescence computed tomography as a novel hybrid modality for tumor profiling, with a focus on breast cancer. The pnCCD silicon sensors produced by MPG HLL, Munich, have been chosen for the proof-of-principle studies. Fluorescence photons are generated when gold nanoparticles are excited by incident X-rays and are detected by the pnCCD. A specific system has been designed to operate up to four pnCCDs, including a cooling system to stabilize sensors' temperature between 0ºC and 20ºC, and it is under construction. Simulations are also performed which support the system design.

Abstract

In the context of the "Small Animal Proton Irradiator for Research in Molecular Image-guided Radiation Oncology" (SIRMIO) project, a high-resolution depth-of-interaction (DOI) LYSO-based detector has been developed for a small-animal in-beam PET scanner. In addition to PET applications, the DOI detector may also be suitable for the detection of high-energy prompt gamma rays originating from excited nuclei such as 12C and 16O, enabling potential applications in Compton camera imaging for ion-beam therapy monitoring. However, the interaction mechanisms of high-energy gamma rays differ from those of 511 keV annihilation gamma rays, particularly in terms of the relative contributions of photoabsorption and Compton scattering processes. In this study, we experimentally investigated the performance of the DOI detector for high-energy gamma-ray detection to gain a better understanding of its applicability to prompt gamma imaging. The detector consists of a three-layer pixelated scintillation block coupled to a 64-channel silicon photomultiplier array. The use of the PETsys TOFPET2 ASIC, employed in the Compton camera MACACOp developed by the IRIS group, is a potential alternative to the current electronics employed in the SIRMIO project, which enables individual channel readout. The study demonstrates the feasibility of operating the detector with PETsys electronics, and characterizes its response with 60Co and 22Na sources.

Abstract

Positron emission tomography systems are becoming increasingly complex due to the growing number of detector channels and the large amount of data generated, especially in total-body imaging configurations. In this work, we present PETRARCA, a positron emission tomography detector system integrating an analog neural network ASIC (ANNA) for real-time edge computing of gamma-ray interaction coordinates within a monolithic scintillation crystal. The system consists of a 32 mm × 32 mm × 10 mm monolithic LYSO crystal coupled to an 8 × 8 SiPM matrix read out by dedicated front-end electronics. The detector architecture includes both a conventional digital acquisition path and a parallel analog inference path based on the ANNA ASIC, enabling simultaneous acquisition of sensor data and hardware neural-network predictions. A first evaluation of the system has been carried out using simulated data and the real ASIC response to emulate a reduced-scale configuration using a 4 × 4 SiPM array coupled to a 26 mm × 26 mm × 10 mm monolithic crystal. The performances of the ASIC in predicting the interaction coordinates were tested, and proved to have a mean absolute error (MAE) of around 1 mm on both the x and y axes. The preliminary results demonstrate the feasibility of analog neural-network edge computing for spatial localization in PET detectors and support further developments toward fully integrated real-time detector systems.

Abstract

Lutetium oxide–based scintillators are of growing interest for positron emission tomography (PET) because of their high density and high effective atomic number, which provide efficient stopping of 511 keV annihilation photons. Lanthanum-doped $(Lu,Y)_2O_3$ (LYO:La) is a transparent ceramic variant that retains the favorable stopping power of Lu_2O_3 while being easier to fabricate, making it an attractive candidate for next-generation PET detector arrays. In this work we report a scintillation characterization of LYO:La pixels in two geometries relevant to PET, 1×1×10 mm^3 for high-resolution preclinical and dedicated-organ imaging, and 3×3×10 mm^3 for whole-body clinical systems. Pixels were cut from LYO:La ceramic disks, polished on all faces, and evaluated with a range of side reflectors (Teflon, Tyvek, ESR film, and Spectralon) in both flat and upright coupling orientations. We measured X-ray-excited radioluminescence emission spectra, ^{22}Na (511 keV) pulse height spectra, relative light yield, energy resolution, scintillation decay time profiles, and timing resolution. The results illustrate the influence of pixel geometry, coupling face, and reflector choice on light collection and energy resolution, and show that LYO:La pixels offer a promising combination of stopping power, light yield, and timing performance for PET detector modules.

Abstract

Dynamic medical X-ray imaging requires detectors that combine high quantum efficiency, low residual lag, and high spatial resolution without the optical spread and afterglow of scintillator-based flat panels. We report a fully inorganic perovskite-based direct-conversion perovskite X-ray imager fabricated from phase-pure orthorhombic Cesium Lead Bromide (CPB) sensor material and integrated with active-pixel readout arrays. Phase-pure CPB was obtained by controlled crystal growth and converted into dense blade-coated films; non-phase-pure starting materials containing secondary phases produced nonuniform films and degraded images, confirming the importance of phase control for reproducible detector performance. The optimized CPB detector demonstrated high linear X-ray response, sensitivity of 55,400 μC $Gyair^{-1}$ cm^{-2} at 30 keV and 0.5 V/μm, a limit of detection of 417 pGyair s^{-1}, a mobility-lifetime product of 8.0 × 10^{-4} cm^2 V^{-1}, and a calculated detective quantum efficiency near 85% at practical dose levels. In flat-panel imaging, CPB imagers reached 6.9 lp/mm at 20% modulation transfer function on a 100 μm-pitch amorphous-silicon array and resolved 20 lp/mm after integration with a CMOS readout. Most importantly for low-lag medical applications, improvements in phase purity and charge-transport stability reduced residual detector lag from 8.9% to 1.1%. These results show that all-inorganic perovskite direct conversion can provide a path to low-dose, low-lag, high-resolution imaging for fluoroscopy, tomosynthesis, dental cone-beam computed tomography, and other image-guided procedures.

Abstract

Large-area microchannel plate photomultipliers (MCP-PMT) such as the Large-Area Picosecond Photon Detector (LAPPD) and High-Rate Picosecond Photon Detector (HRPPD), are attractive for time-of-flight positron emission tomography (TOF-PET) due to their superior single-photon time resolution (SPTR) and low-cost potential. However, when coupling them with popular TOF-PET scintillators, it was previously reported worse-than 250 ps coincidence time resolutions (CTR) for annihilation photons. In this work, by applying a custom high-frequency (HF) amplifier to the outputs of an HRPPD (10×10cm^2 window) coupled to a 3×3×3 mm^3 LGSO crystal and an SiPM-based reference detector, we measured a 144 ps CTR. In addition, we showed that individual crystals of a 4×4 array of 3×3×10 mm^3 LYSOs can be resolved using this HRPPD whose output was 4×4 pads having a 25 mm pitch. We also constructed a detector model for investigating key factors affecting CTR. These factors include scintillation yield, light transport in the crystal and HRPPD window, photon detection efficiency and charge collection of the HRPPD, and electronics contributions, with parameters derived from analytical calculations, Geant4 simulations, or experimental measurements. This model predicted a CTR that was consistent with the measured value. Based on this model, a development roadmap with quantitative performance targets and near-term milestones is presented.

Analytical modeling and inclusion of object scatter in non-TOF 3D PET for low-count data (#1275)

Jorge Roser, Hong P. Vo, Magdalena Rafecas

Universität zu Lübeck, Institute of Medical Engineering, Lübeck, Germany

This work was supported by the European Union's Horizon 2024 research and innovation programme under the Marie Skłodowska-Curie grant agreement no. 101207067, and partly by the German Research Foundation (DFG) under grant agreement no. 508064995.

Abstract

Compton scattering in Positron Emission Tomography (PET) is commonly seen as an important degrading factor for the image quality. In particular, object scattering is known to reduce image contrast and distort quantification. Conventional scatter correction techniques do not model scatter directly in the system matrix, despite its potential to better handle low-count data scenarios. In this work, we propose an analytical model for single Compton scattering events and subsequently derive expressions of the system matrix and sensitivity. We validate the obtained expressions with Monte Carlo simulations. Ongoing work includes studying the impact of such approach by using low-count simulated data, and a comparison of the proposed method with conventional scatter correction techniques.

Noise Modeling of Three Material Dual Energy Computed Tomography with a Pathlength Constraint (#1443)

Andrew E. Ferretti, Emil Sidky, John Paul Phillips, Xiaochuan Pan

University of Chicago, Department of Radiology, Chicago, USA

This work is supported in part by NIH grant No. R01-CA287302. The contents of this article are solely the responsibility of the authors and do not necessarily represent the official views of the National Institutes of Health.

Abstract

Dual energy computed tomography (DECT) utilizes transmission measurements through a sample with two distinct X-ray spectra to produce a two material decomposition. By introducing a path-length constraint to DECT measurements, it is possible to obtain a three material decomposition. In both cases, the stability of the resulting decompositions and noise properties of the virtual monochromatic images (VMIs) are sensitive to acquisition choices like beam energy. We aim to extend a theoretical noise-propagation framework for choosing optimal beam energies and VMI energy for two material decompositions to the three material case. We then demonstrate the utility of this framework for a proposed use-case of contrast enhanced breast tomography. In particular, by assuming linear propagation of noise through material sinogram estimation and filtered backprojection, a compound Poisson noise process in X-ray measurements, and Gaussian-distributed distance constraints, we obtain analytic expressions for the Jacobian of the material sinogram-to-data transformation, the variance of VMI pixels, and the VMI contrast to noise ratio (CNR). We then use the VICTRE software to generate a realistic computational breast phantom, modeled as consisting of glandular tissue, adipose, and iodine contrast agent. For this phantom, we find that tube potential pairings of 30-40 kVp and 55-80 kVp give a high value of the material sinogram-to-data transformation Jacobian determinant, indicating good stability and minimal noise propagation. For this phantom and spectra, we compare analytically predicted and empirically realized VMI CNR versus monoenergy, and find good agreement between them with a maximum CNR of 9.6 for a VMI monoenergy of 65.5 keV in both cases.

Optimization of Pinhole Diameter in Fully Stationary Multi-Pinhole Brain SPECT: Prioritizing Spatial Resolution via CNN-Based Correction

(#1530)

Takumi Akatsuka[1], Koichi Ogawa[2]

[1] Hosei University, Applied Informatics, Graduate School of Science and Engineering, Koganei, Japan; [2] Hosei University, Applied Informatics, Faculty of Science and Engineering, Koganei, Japan

Abstract

Multi-pinhole SPECT enables static data acquisition without rotating the detectors, reducing patient burden. In brain SPECT, particularly for diagnosing neurodegenerative diseases like Alzheimer's, high spatial resolution is critical for visualizing minute regional functions. However, increasing the number of pinholes to secure sufficient sensitivity causes projection overlaps on the detector. Furthermore, physical factors such as gamma-ray attenuation and scattering within the object degrade the quantitative accuracy of reconstructed images. In addition to these issues, a significant trade-off exists regarding the pinhole aperture size. While a larger diameter (e.g., 5 mm) increases photon counts and reduces statistical noise, it exacerbates projection blur and degrades spatial resolution. Conversely, a smaller diameter (e.g., 2 mm) preserves resolution but suffers from increased noise. Previously, we proposed a convolutional neural network (CNN) approach using U-Net++ for a three-detector multi-pinhole SPECT that simultaneously performs overlap separation and various physical corrections. In this study, we applied this framework to brain SPECT to determine the optimal aperture size by comparing 2-mm and 5-mm pinhole diameters. Our results demonstrated that the 2-mm aperture, which maintains spatial resolution, outperformed the 5-mm aperture across quantitative image quality metrics, including NMSE, PSNR, and SSIM, confirming its superiority for detailed brain imaging.

Validated Optical Simulation for High-Energy Gamma Response in a 3-Layer LYSO DOI Detector (#1668)

Shan Jiang, Giulio Lovatti, Francesco Evangelista, Peter Thirolf, Katia Parodi, Munetaka Nitta

Ludwig-Maximilians-Universität München, München, Germany

Abstract

We have developed a 3-layer staggered LYSO de tector with DOI capability within the project SIRMIO (Small animal proton irradiator for research in molecular image-guided radiation-oncology) for proton range verification via PET imag ing. To evaluate the feasibility of detecting prompt gamma rays for quasi-instantaneous monitoring of proton beams, we propose a workflow that includes the validation of optical simulation settings and the implementation of the saturation effect of the SiPM photonsensor in the Geant4 simulation. Measurement data with ^{152}Eu, ^{22}Na and ^{137}Cs radioactive sources are utilized for modeling the saturation effect of SiPM, and also for validating optical boundary settings in Geant4. The measured spectra of ^{22}Na and ^{137}Cs point sources are well reproduced with the proposed simulation workflow. The responses to prompt gamma rays are then simu lated. According to the floodmaps and profiles, LYSO pixel can be identified at 2.2, 4.4 and 6.2 MeV, but the contrast decreases strongly when energy reaches 6.2 MeV. The peak-to-valley ratios drop by up to 53% at 4.4 MeV and 62% at 6.2 MeV (relative to 2.2 MeV), primarily due to the energy deposition occurring more frequently in multiple LYSO pixels. These predictions suggest the detector’s potential for detecting prompt gamma rays, while accurately recovering or rejecting inter-crystal scatter events is essential to maintain detector performance at higher gamma energy.

Abstract

Mesh-type Reference Computational (MRCP) Phantoms provide anatomically realistic tetrahedral organ structures, but their practical use in OpenGATE-based imaging and dosimetry simulations remains limited. In our previous work, a simplified tetrahedral phantom was imported using a tessellated-solid-based workflow and evaluated with heart and body geometries. In this study, we extended the approach to a whole-body tetrahedral phantom framework using parameterised tetrahedral geometry construction and region-aware dose scoring. The updated workflow reads mesh, material, organ-region, and visualization information, constructs the complete phantom in OpenGATE, and enables selected-organ three-dimensional dose scoring while preserving full-phantom particle transport. A copy-number-based filtering method was introduced to associate tetrahedral elements with anatomical regions, avoiding material-name-based selection. The complete phantom, including all anatomical organs, was successfully loaded with a memory usage of 23.84 GB. Three-dimensional deposited energy and dose distributions were generated for selected organs. Multi-threaded performance was evaluated using 8 million x-ray beam particles, reducing computation time from 2453.13 s with 1 CPU thread to 429.43 s with 8 CPU threads, corresponding to a 5.7-fold speed improvement. In the 8-thread simulation, dose scoring for four selected organs, including blood, heart wall, and both lungs, was completed in approximately 5 minutes. These results demonstrate the feasibility of multi-threaded, organ-specific MRCP dosimetry and provide a basis for extending mesh-type phantom simulation to CT, PET, SPECT, and linac workflows in OpenGATE.

MIC-10-065

Inter-Crystal Scattering in LYSO-SiPM PET: Integrated Analysis via Geant4/GATE Simulation, CNN, and Multi-Pitch Experiments (#1859)

Tianyi Deng, Qinghua Zhang, Hongqiang Zhang, Xiangdong Cai, Chunhui Zhang, Yongzhi Yin

Lanzhou University, School of Nuclear Science and Technology, Lanzhou, China

Abstract

This study integrates GEANT4/GATE Monte Carlo simulations with hardware experiments to investigate and correct inter-crystal scattering (ICS) in Lutetium Yttrium Oxyorthosilicate (LYSO) Positron Emission Tomography (PET) detectors. In the simulation phase, 10^7 valid events from a 511 keV gamma-ray point source were tracked across a 16 x 16 LYSO array (2.1 mm pitch) to analyze 3D energy spread and depth of interaction (DOI) characteristics. To correct ICS-induced parallax errors, we designed a physics-guided Convolutional Neural Network (CNN) with an energy masking constraint to recover the initial interaction coordinates. Furthermore, we established a physical experimental platform using arrays of various pitches (2.1 mm, 3.2 mm, and 4.1 mm). Deploying the pretrained CNN on physical hardware and conducting preliminary iterative training with empirical data demonstrated the predictive potential of machine learning for measured signals. During system image reconstruction, perfect CNN prediction of ICS events could theoretically improve spatial resolution from 1.45 mm to 1.21 mm. By synergistically applying algorithmic ICS correction and DOI information, the full width at half maximum (FWHM) can be further compressed to 0.99 mm. This study provides a conceptual solution and initial attempt for mitigating inter-crystal scattering in future high-resolution PET detectors.

MIC-10-068

Design of a brain SPECT scanner based on high intrinsic resolution CZT detectors and multi-pinhole collimators (#1985)

Kjell Erlandsson[1], Francesco Fraioli[1], Alexander Cherlin[2], Brian F. Hutton[1], Kris Thielemans[1]

[1] University College London, Institute of Nuclear Medicine, London, UK; [2] Kromek Ltd, Department of imaging, Sedgefield, UK

This work was supported by funding from the UKRI EPSRC Impact Acceleration award to UCL (EP/X525649/1). INM staff are partly funded by the NIHR University College London Hospitals Biomedical Research Centre.

Abstract

SPECT is useful for investigating a range of neurological and psychiatric conditions, such as Parkinson's disease, epilepsy and schizophrenia. Most clinical brain SPECT studies are performed with rotating gamma-cameras with

parallel-hole collimators, which results in sub-optimal image quality. Multi-pinhole (MPH) collimators can provide an improved sensitivity vs. resolution trade-off, while Cadmium-Zinc-Telluride (CZT) detectors offer better intrinsic spatial resolution as well as superior energy resolution compared to scintillation detectors. In collaboration with Kromek Ltd, we have developed a molecular breast imaging system based on CZT detectors and MPH collimators. Here we report initial results on designing a dedicated brain SPECT scanner using similar technology. The system will consist of a polygon of planar detectors and will be completely stationary, allowing for dynamic imaging. We performed computer simulations for various design configurations, based on a 20-cm diameter spherical field-of-view (FOV), assuming an intrinsic detector resolution of 0.4x0.4 mm and a depth-of-interaction (DOI) resolution of 1 mm. The simulations were based on an analytical system model, and images were reconstructed using an ML-EM algorithm. Our initial evaluations involved two different digital phantoms: A grid of 7x7 point-sources with a non-zero background; and the Hoffman brain phantom. With the target resolution set to 9 mm at the center and a degree of multiplexing of ~30%, the sensitivity was ~6×10^{-4}. An average reconstructed resolution of ~5 mm FWHM was obtained, going from 9 mm at the center down to 2-3 mm towards the edge of the FOV. In conclusion, our initial results show that high image quality can be obtained with this type of SPECT system.

Modeling analog SiPMs with temporal crosstalk integration for fast timing in medical imaging (#2021)

Nicolaus Kratochwil[1], Emilie Roncali[1], Gerard Ariño-Estrada[1,2]

[1] University of California, Davis, Department of Biomedical Engineering, Davis, USA; [2] Barcelona Institute of Science and Technology in Barcelona, Institut de Fisica d'Altes Energies, Barcelona, Spain

This work was supported by NIH grant R01EB034062.

Abstract

Silicon photomultipliers (SiPMs) coupled to scintillators are widely used in medical imaging, particularly in fast-timing applications such as time-of-flight positron emission tomography (TOF-PET) . While significant progress has been made in modeling detector response and correlated noise, recent advances in SiPM technology and fast readout electronics require a reassessment of the full analog signal formation process. In particular, the transition from idealized digital timestamps to realistic analog signals introduces information loss due to bandwidth limitations, electronic noise, and correlated effects such as optical crosstalk.

We present a comprehensive simulation framework that bridges this gap by modeling both analog waveform formation and generation-dependent optical crosstalk with explicit temporal structure. The framework enables systematic separation of different degradation mechanisms affecting timing performance. We investigate the impact of bandwidth limitation, electronic noise, and correlated noise on coincidence time resolution, as well as the information loss transitioning form digital to analog signals.

Our results show a clear degradation of timing resolution when moving from ideal timestamps to realistic analog

readout conditions, in agreement with experimental measurements. Furthermore, we observe that optical crosstalk can, in certain scintillator configurations, improve timing performance by effectively enhancing early signal amplitude, while simultaneously degrading higher-level temporal information relevant for event characterization. The presented framework provides a flexible tool for disentangling these effects and guiding SiPM and readout optimization for future fast-timing detector systems.

The project is partially supported by the German Research Foundation (DFG) under grant agreement no. 496099829 and the DFG Cluster of Excellence PMI under grant agreement no. 390884018.

Abstract

MERMAID is the first PET scanner prototype dedicated to study small aquatic animals. Particularly, it aims to support the use of adult zebrafish as a model of human diseases. The current prototype, which consists of four detection modules composed of LYSO:Ce crystals, has demonstrated the capability of providing images with submillimeter resolution. An extension of MERMAID by another four modules is planned, aimed to increase the system sensitivity and allow for shorter scan times, making it more suitable for in-vivo imaging. In the presented work, various configurations for the extended MERMAID system are characterized by means of simulations and tailored reconstruction framework; modifications of imaging protocol for the system are investigated.

Design and Modeling of BetaBox 2.0: a System for Quantitative Measurement of Beta Emitters in Single Cells (#2271)

Kyle Klein, Juan Alex Leal Doblado, David Prout, Peter Clark, Mike van Dam, Arion Chatziioannou

University of California Los Angeles (UCLA), Pharmacology, Los Angeles, USA

This work is supported in part by the National Institute of Health under Grants R01CA289908, and T32EB002101.

Abstract

Single cell radiation measurements are an integral part of interrogating the biological heterogeneity of cancerous tumors. Identifying cell types present in bulk tumors via FDG uptake can elucidate cell types resistant to treatments, that would potentially be obscured via macroscopic FDG PET imaging. The BetaBox 1.0 was previously constructed to perform these single cell radiation measurements, but suffers from a lack of scale and inability to isolate cells after radiation measurement for further study. To address these challenges, we are constructing the BetaBox 2.0, which will be a high-sensitivity, low-noise device capable of performing many simultaneous single cell radiation measurements via the detection of beta particles in a pixelated array of organic scintillators coupled to SiPMs. The design of BetaBox 2.0 is considered and modeled in GATE simulations, which are used to determine an optimal organic scintillator thickness for the device. These simulations are then expanded on via experimental measurements taken with a SiPM pixel read out by PETsys readout electronics. These datasets jointly suggest the BetaBox 2.0 will be capable of isolating the signal from single cells, and quantitatively assessing their radiation uptake.

Hardware Ray-Tracing-Accelerated Optical Photon Transport in TOPAS on Apple Silicon (#2319)

YoungMoon Goh, Keum M. Back, Ui-Seob Lee, Sung-Woo Kim, Si Y. Song

Asan Medical Center, Department of Radiation Oncology, Seoul, South Korea

This work was supported by the National Research Foundation of Korea (NRF), funded by the Ministry of Science and Information and Communication Technology of Korea (grant number 2026OK9045).

Abstract

Optical photon transport in scintillator-based imaging detectors dominates TOPAS Monte Carlo wall time because each primary spawns tens of thousands of secondary photons, and TOPAS itself has no released GPU backend. We present MetalOpticalPhoton, a TOPAS extension that ports the optical physics chain to Apple Metal hardware ray tracing while reusing existing TOPAS material/surface/geometry tables. On an Apple M3 Ultra (80 GPU cores), execution wall time on a 100K-event scintillator-plus-lens benchmark is 25–28× shorter than a 30-thread M3 CPU baseline and about 10× shorter than a 90-thread AMD 7995WX baseline, sustaining roughly 33×10^6 photons/s GPU throughput. Two corrections to vanilla OpenTOPAS—a parallel-world envelope coincident-boundary loop suppressing 75–80% of the sensor-integrated CPU optical fluence, and a primary polarization initialization typo—were required for a self-consistent CPU reference and are relevant to TOPAS optical Monte Carlo independently of GPU acceleration. After patching, CPU–GPU agreement reaches the sub-1% level reported for production GPU optical Monte Carlo (sensor-integrated fluence sum ratio 0.993 ± 0.002 over five seeds).

Identification of ICS Pixels in a high-resolution 3-Layer DOI-PET Detector Using a CNN (#2619)

Shan Jiang, Giulio Lovatti, Francesco Evangelist, Peter Thirolf, Katia Parodi, Munetaka Nitta

Ludwig-Maximilians-Universität München, München, Germany

Abstract

We have developed a 3-layer staggered LYSO DOI detector for the SIRMIO (Small animal proton irradiator for research in molecular image-guided radiation-oncology) project, with a crystal pitch of 1.0 mm. Due to the small crystal size, inter-crystal scatter (ICS) events degrade spatial resolution, while discarding them causes significant sensitivity loss. In our detector, ICS events account for approximately 50% of all interactions at 511 keV and result in a median lateral positioning error of approximately 2 mm. To solve this problem, we propose a dual-head convolutional neural network (CNN) for separating the 8×8 MPPC total response of two-pixel ICS events into two individual response matrices, from which the pixel positions and energy fractions can be obtained—a precondition for recovering the ICS events. The CNN correctly identifies both scattering pixels in 69.3% of test events, and in 26.4% of cases one pixel is correctly identified. Among the events with one pixel mismatched, the lateral error of the misidentified pixel falls within 1.0 mm in 91.0% of cases. Meanwhile, the median energy fractions prediction error is 0.016 per pixel. The results demonstrate that CNN-based MPPC response decomposition can serve as the enabling foundation for complete ICS recovery in 3-layer staggered DOI detectors, addressing a limitation explicitly acknowledged in recent physics-based ICS studies.

Abstract

PET systems require (among others) normalization corrections for the geometric sensitivity of the scanner, the result of the spatial arrangement of the detector crystals and energy readout area. It is estimated for a given extent of the photon energy acceptance window, and must be re-estimated if the lower energy threshold (LET) is changed, e.g. when optimizing the number of noise-equivalent counts for a given object, or to improve joint estimation of activity and attenuation. To investigate the effect of changing the LET on the geometric sensitivity, we performed a simulation study in SimSET and compared sensitivity sinograms, reconstructions and properties of accepted photons. We found that the effects are dependent on detector location and photon incidence angle, and likely due to the finite extent of the energy readout area.

MIMOSA: Medical IMaging MOnte Carlo Simulation Algorithms for fast proton therapy range monitoring (#2751)

Declan D. Garvey, Gabriela Llosá, Fernando Hueso-González

IFIC, CSIC-UV, Valencia, Spain

This work has been funded by the Conselleria de Educación, Investigación, Cultura y Deporte (Generalitat Valenciana), Spain, under grant number CDEIGENT/2019/011, by CSIC's JAEPRE23-19 grant, and by the MIDAS project PID2022-143246OB-I00 (MICIU/AEI). IFIC is supported by the Severo Ochoa Center of Excellence grant CEX2023-001292-S funded by MCIU/AEI

Abstract

Monte Carlo simulations play a vital role in many aspects of proton therapy treatment, including proton depth of penetration monitoring. A key limiting factor of full simulation engines is computation time: simulations can take several days, far longer than the time between treatment fractions. This project aims to develop a Monte Carlo simulation software, MIMOSA, for prompt gamma-ray based proton range verification, that is fast enough to be deployed before the next treatment fraction. Clinically acceptable gamma pass rates above 99% for 2%/2 mm and 97% for 1%/1 mm with respect to TOPAS were achieved on both homogenous and heterogenous phantoms. To benchmark computational speed, state-of-the-art GPU codes MOQUI and FRED were tested on the same computer. Comparatively, MIMOSA achieved a notable speed increase, able to simulate 1e9 primary protons with a 200 MeV energy in approximately 3 minutes. Along with maintaining accuracy and increasing computational speed, the project uses the hardware agnostic SYCL standard, and will be available with an open-source license and extensive documentation. Ongoing work is devoted to simulating realistic radiotherapy treatment plans, and including prompt gamma-ray transport and detector response.

Abstract

Computed tomography image quality is degraded by scattered photons, which reduce image contrast and quantitative accuracy. Time-of-flight-based scatter rejection has been proposed as a method to distinguish primary and scattered photons using their arrival-time differences, but the influence of beam filtration under polychromatic x-ray spectrum has not been fully evaluated. This study investigated the effects of tube voltage and beam filtration on time-of-flight-based scatter rejection using Monte Carlo simulation. X-ray spectrum were generated at 40 and 120 kVp, and four filtration conditions were compared: no filter, 1.06mm aluminum, 0.15mm copper, and 0.6mm tin. Polymethyl methacrylate phantoms with thicknesses of 50 and 200 mm were simulated. Scatter rejection performance was evaluated using the scatter rejection rate as a function of timing jitter from 0 to 1000 ps, and the area under the curve was used as a summary metric. At 120 kVp, tin filtration increased the area under the curve by 11.1% in the 200mm phantom and by 30.6% in the 50mm phantom compared with the no-filter condition. In contrast, at 40 kVp, the filtration effect was small, with a maximum area under the curve difference of 0.010 in the 50mm phantom. These results indicate that tin filtration improves timeof-flight scatter rejection at 120 kVp, whereas filter optimization has a limited effect at 40 kVp.

Abstract

Hadron therapy is a highly conformal cancer treatment technique that enables superior dose delivery to the tumor while sparing surrounding healthy tissues. However, its full clinical benefit is still limited by uncertainties in proton range within tissue, mainly due to the indirect estimation of ion stopping power from X-ray CT images. These uncertainties lead to safety margins that reduce treatment precision. Real-time, high-accuracy ion-range verification is essential to improve dose delivery and further enhance the therapeutic potential of proton therapy. Among the available approaches, PGI and PET are regarded as the most promising, as they provide complementary information. PGI offers direct correlation with the Bragg peak during irradiation, whereas PET yields high-resolution activity distributions from beta+ emitters produced along the proton path.

In this work, we report recent developments and experimental results obtained with a hybrid PGI-PET system for in situ proton range verification. The system is based on four high-efficiency two-plane Compton imagers arranged in a cross configuration, specifically optimized to enhance PGI sensitivity at the expense of a reduced PET field of view. Experimental campaigns were carried out at commercial IBA Proteus Plus and Proteus One proton therapy facilities using 100 and 125 MeV pencil beams delivered at minimum clinical currents. Polyethylene phantoms were irradiated at controlled positions and data were acquired during both in-spill and off-spill periods.
The first reconstructed 2D images demonstrate that PGI can directly identify the Bragg peak position through the maximum of the PGI distribution over a broad field of view, while PET provides a narrower and higher-resolution distribution associated with the induced beta+ activity. These results confirm the feasibility and complementarity of the hybrid PGI-PET approach and support its potential for accurate, clinically relevant proton range verification.

Abstract
Cell tracking in vivo is a key challenge in translational medicine. Positron emission tomography (PET) and magnetic resonance imaging (MRI) offer complementary strengths for this task, yet the validation of tracking algorithms against a reliable ground truth remains unresolved. Fluorescence microscopy can fulfill this role, but its integration into the highly constrained PET/MRI environment poses significant technical challenges. Here, we present a fluorescence microscope (FM) designed for simultaneous operation inside a small-animal PET/MRI scanner, with all custom structural and housing components 3D printed in polylactic acid (PLA). The assembled instrument has a total length of 95 cm and fits within the 35 mm PET insert bore, accommodating sample diameters of up to 21 mm. The imaging probe is rotated via a non-ferromagnetic, friction-driven mechanism, enabling multi-angle acquisition without repositioning the sample, and reliable rotation over the full 360° range was demonstrated under manual control. The system follows an epi-fluorescence configuration with 10× magnification, an excitation wavelength of 488 nm, and a 500 nm longpass filter in the detection path. Characterization with a calibration slide and a Convallaria majalis test specimen yielded a pixel pitch of 0.144 µm/pixel (6.96 pixels/µm), a spatial resolution of 2.32 µm (FWHM), a signal-to-noise ratio (SNR) of 7.21, and a field of view (FoV) of 0.55 × 0.31 mm2 (3816 × 2160 pixels), sufficient to resolve individual cells. These results establish the feasibility of integrating fluorescence microscopy into a PET/MRI scanner and provide the basis for future multimodal cell tracking studies with a reliable optical ground truth.

Abstract

We report a design study for a combined preclinical scanner that integrates PET, SPECT, and MRI for simultaneous acquisition of PET, SPECT, and MR images for broad-band multi-isotope imaging capability critical for theranostics applications. The PET subsystem provides a very high-sensitivity and benefits from a wide variety of existing tracers. The SPECT subsystem allows for broad-band multi-isotope imaging capability critical for imaging therapeutic radioisotopes and their daughters. MRI offers unmatched soft-tissue contrast and high-resolution anatomical reference. The PET/SPECT insert consists of 12 detector rings. The central four PET rings are integrated with four rings of micro camera elements (MCEs) that are "looking at" the object through the small gaps between the PET detector blocks. This compact design provides approximately 16% PET sensitivity at the center and 1-mm PET imaging resolution across the 8-cm transverse by 28-cm axial FOV. The 64 CZT SPECT cameras provide approximately 1-mm spatial resolution over a 6-cm transverse and 9-cm axial FOV. To support simultaneous PET/SPECT operation, the design incorporates our previously developed anti-coincidence rejection strategy to suppress PET-induced contamination in SPECT data. Prior F-18/Tc-99m PET/SPECT simulations demonstrated up to 83.7% rejection of scatter contamination in projection-domain analysis, supporting the feasibility of acquisition-level cross-modality rejection. These design elements resulted in a compact and high performance tri-modality imaging platform for simultaneous PET/SPECT/MR imaging for preclinical theragnostic applications.

Abstract

We previously proposed a Broadband Ultrasensitive Gamma Imager (BUGI) that uses a sensing collimator imager to encode and detect gamma rays without a metal collimator. When combined with fast scintillators, this approach enables simultaneous high-sensitivity SPECT and time-of-flight-capable PET imaging, with potential applications in monitoring alpha-particle radiopharmaceutical therapy (RPT). Unlike conventional simultaneous PET/SPECT systems, which use high-energy collimators that reduce PET sensitivity to SPECT levels, BUGI raises SPECT sensitivity toward that of PET.In this study, we evaluated two preclinical BUGI detector designs using GATE Monte Carlo simulations: a pinhole-inspired geometry and a parallel-hole-inspired geometry. The scanner consists of an octagonal arrangement of 8 detector blocks, each containing 1 × 4 arrays of self-collimating mini-modules built from 3×3×3 mm³ GAGG crystals. A dual-isotope cylindrical phantom was simulated with a ^{99m}Tc background, a ^{99m}Tc spherical tumor, and an ^{18}F spherical tumor, with a tumor-to-background ratio of 4:1. SPECT events and PET

coincidence events were reconstructed independently using a GPU-based MLEM framework.Both detector geometries produced usable simultaneous SPECT and PET images with comparable tumor contrast . The parallel-hole design showed better background uniformity, improved preservation of the cylindrical phantom shape, and sharper tumor edges.The pinhole design showed an octagonal artifact pattern that may be reduced with increased angular sampling. PET images were sharp and visually similar between the two designs. Future work will focus on developing and validating multi-energy-window SPECT and PET reconstruction methods for the BUGI system.

A Dual-Ring Super-Resolution PET System (#1259)

Youdong Lang[1,2], Qingguo Xie[1,3], Chien-Min Kao[4]

[1] Huazhong University of Science and Technology, Biomedical Engineering Department, Wuhan, China; [2] Huazhong University of Science and Technology, Institute of Artificial Intelligence, Wuhan, China; [3] University of Science and Technology of China, Department of Electronic Engineering and Information Science, Hefei, China; [4] University of Chicago, Department of Radiology, Chicago, USA

This work was supported in part by the Key Program of National Natural Science of China under Grant 62131009.

Abstract

Building upon previous works that explored the feasibility of super-resolution (SR) positron emission tomography (PET) by applying the principle of structured illumination microscopy (SIM), in this work we propose the concept of a dual-ring SR PET system design. Such a PET system contains a rotatable inner detector ring that serves the dual purpose of creating the needed measurement modulation for performing SIM-based SR as well as increasing event detection to eliminate a major drawback of the previous approach in which the modulator could considerably diminish the imaging sensitivity. We simulated a 2d PET system comprising 576 4.2 mm (transaxial) x 4.2 mm (axial) x 20 mm (radial) LYSO crystals on a 770 mm diameter ring. On the other hand, the inner ring consisted of repeating 2.8 mm-width attenuating material or detector and 5.6 mm-width air. The attenuating material was either 5 mm thick tungsten (W) or 10 mm thick LYSO. The outer detector was 20 mm thick LYSO. Axially, the inner ring was uniform and had the same 4.2 mm length as the outer detector ring. An SR dataset was made of three measurements acquired at three rotational positions of the inner ring. We also considered point-spread function (PSF) reconstruction when not using the inner ring, and also the situation when detector wobble motion was introduced to increase sampling. Our simulation results show that the dual-ring image can resolve 1.2 mm sources in the case of noise-free data and the image quality is visually superior to the PSF and Wobble+PSF images. For a noisy data set, it yields an overall better image quality than the other two SIM-based SR images using W or LYSO modulators for it has higher coincidence detection sensitivity. Quantitative performance evaluation based on the contrast-recovery-coefficient versus the background noise also shows superior results with the dual-ring system.

Abstract

Dedicated brain positron emission tomography (PET) systems can achieve higher sensitivity and spatial resolution than whole-body PET scanners due to their compact detector geometry. However, the reduced detector aperture introduces parallax error, making depth-of-interaction (DOI) capability important for maintaining spatial resolution uniformity across the field of view. In this work, we present a comprehensive performance evaluation of a DOI-enabled dedicated brain PET system based on light-sharing window (LSW) detector technology. The system consists of ten detector panels with an axial field of view of 280.6 mm and employs 2.0 × 2.0 × 20.0 mm^3 LYSO crystal arrays with DOI encoding capability.Performance measurements were conducted following the NEMA NU 2-2018 standard, including spatial resolution, sensitivity, count rate performance, scatter fraction, and time-of-flight (TOF) resolution. The measured sensitivity reached 14.31 cps/kBq at the center of the field of view and 15.08 cps/kBq at a radial offset of 10 cm. The peak noise-equivalent count rate (NECR) was 39.54 kcps at 5.11 kBq/mL. The TOF resolution was 298 ps at peak NECR and improved to 281 ps at low activity concentrations. Spatial resolution measurements demonstrated that DOI encoding significantly mitigated parallax error at large radial offsets. Preliminary clinical imaging studies further demonstrated the capability of the proposed system for high-resolution brain PET imaging

Abstract

General-purpose positron emission tomography scanners often face challenges with the high-frequency motion and small target volumes inherent in cardiac imaging. This study introduces a heart-dedicated positron emission tomography prototype featuring twenty detector panels in a cylindrical geometry with a 493.28 millimeter aperture and a 236.4 millimeter axial field of view. The detectors utilize lutetium-yttrium oxyorthosilicate crystals coupled to multi-pixel photon counters with depth-of-interaction capability. Performance was validated through Geant4 Application for Tomographic Emission simulations, detector bench tests, and in vivo experiments. Results demonstrate a coincidence resolving time of 234 picoseconds full width at half maximum and a spatial resolution of 1.0 millimeter under idealized conditions. Furthermore, electrocardiogram-gated imaging in rat and rabbit models successfully captured eight cardiac phases from end-systole to end-diastole, providing distinct myocardial structures without significant motion blur. These results validate the system's high sensitivity and timing precision, establishing a foundation for extracting functional parameters such as ejection fraction. Future work will implement depth-of-interaction correction across the full field of view to maintain high peripheral resolution for precise cardiovascular research and clinical diagnostics.

Abstract

Positron emission tomography (PET) is an indispensable tool in neuroscience, yet its efficacy in early lesion detection and advanced brain research is often constrained by the fundamental trade-offs between spatial resolution and sensitivity. To surpass these limitations, this study introduces the NeuroEXPLORER with Insert (NXI), a high-performance dedicated brain PET system that integrates Virtual Pinhole (VP-PET) technology into the NeuroEXPLORER (NX) platform. We developed a comprehensive quantitative reconstruction framework incorporating a full suite of physical correction techniques tailored for the NXI's asymmetric geometry. The system's performance was rigorously validated through Monte Carlo simulations using GATE. Point-source evaluations demonstrated a enhancement in overall sensitivity, driven by an increased proportion of high-resolution insert-scanner (IS) coincidence events in the vicinity of the insert. An ablation study performed on uniform cylinder data, demonstrated the effectiveness of the integrated correction suite, including normalization, attenuation, random, and scatter corrections. In Derenzo phantom experiments, the NXI system successfully resolved 0.6 mm hot rods, a benchmark that remained unresolvable by the standard NX configuration. Furthermore, high-resolution digital brain phantom studies confirmed the system's clinical potential, showing a 5.74% increase in data acquisition volume and a 19.31% improvement in the contrast-to-noise ratio (CNR) of gray and white matter compared to the NX system. By synergizing optimized hardware design with specialized reconstruction algorithms, this work verifies that the NXI architecture substantially elevates both sensitivity and spatial resolution, providing a robust technical pathway for the development of next-generation dedicated brain PET instrumentation.

Funding DFG 508064995

Abstract
To improve diagnostic accuracy in hybrid breast imaging, we develop a dedicated PET/MR breast insert for integration into a clinical whole-body PET/MR system. The final insert consists of two cylindrical detector rings (⌀ = 178 mm, height = 95 mm), each comprising five rings with 32 detector blocks per ring. A sparsely populated (18/32 blocks) single-ring prototype was realized, using dual-layer, depth-of-interaction capable 10×10/9×9 LSO scintillator arrays (1.6×1.6×9.8 / 5.2 mm³) and SiPM readout connected via 30 cm flexible cables to MRI-compatible front-end electronics. Detector calibration and bias voltage optimization demonstrated changes in CRT of up to 100 ps between 42-47V. A bias voltage of 45 V was selected as a stable operating point, maintaining consistent energy resolution and coincidence count rates. Reliable crystal identification was achieved for both layers, with a peak-to-valley ratio of 3.7. At this operation point, the prototype achieved energy resolutions of 13.1 ± 1.8% FWHM (top layer) and 11.8 ± 2.4% (bottom layer). CRT depended on the applied energy window, yielding 383 ± 34 ps FWHM for 430–610 keV and improving to 349 ± 32 ps for a 511±50 keV window, while degrading to 483 ± 175 ps for 250–760 keV. Compared to previous system configurations (>500 ps), the updated readout enabled a substantial improvement in timing performance. These results demonstrate robust energy and timing performance of a sparsely populated, DOI-capable PET/MR insert under realistic integration constraints, including extended signal routing and MRI-compatible system design. The findings support the scalability towards a fully populated double-ring system currently under construction, enabling systematic evaluation of PET/MR performance under stress-test sequences and realistic breast imaging conditions within a clinical PET/MR scanner.

Abstract
This work presents a low-cost small-animal PET system based on BGO crystals with depth-of-interaction (DOI) capability. A 10×8 BGO array (1.5×1.5×20 mm³) is coupled to an MPPC array in a 2×2 configuration, and a 6-mm

light-sharing window (LSW) encodes DOI-dependent light sharing. Using a rapid calibration method (vertical line source + histogram matching), the detector achieves an average DOI resolution of 4.9 mm FWHM and an energy resolution of 17.4% at 511 keV. System-level evaluation shows a spatial resolution of 1.43 mm FWHM at the center and resolves 1.5-mm hot rods. The design eliminates labor-intensive mechanical collimation, offering an affordable, maintainable solution for high-sensitivity preclinical imaging.

Abstract
The J-PET (Jagiellonian Positron Emission Tomography) collaboration is developing a large Field-Of-View (FOV) Total-Body J-PET (TB-J-PET) scanner [1,2,3,4] enabling, among others, low dose imaging, short scan times, and dynamic imaging. The key distinctive feature, i.e., the utilization of cost-effective plastic scintillators, could facilitate a wider adoption of large FOV scanners. In this work, we study the benefit of combining the TB-J-PET with a Brain PET Insert (BI) via Monte Carlo simulations. We show that the proposed detector configuration has unique advantages enhancing the spatial resolution. For this purpose, we first developed a rigorous and accurate scheme to estimate spatial resolution from Maximum Likelihood Expectation Maximization (MLEM) reconstructions. We thereby address known challenges of MLEM-based spatial resolution assessment [5], which is discouraged by NEMA standards that continue to rely on the suboptimal Filtered Back-Projection (FBP). We then investigate the impact of the detector geometry on the resolution. The BI uses narrower scintillators than the TB-J-PET (4 vs. 6 mm). We show that this is a resource-efficient approach to achieve high resolution inside the BI, since the coincidences between TB-J-PET and BI (~50% of sensitivity) have particularly low uncertainty. We also show that this detector configuration is geometrically optimal and suppresses the non-collinearity effect. We back up our findings with theoretical analyses. We also investigate other factors influencing spatial resolution, including event selection, detector scattering, phantom scattering, and positron range. We provide intuitive insights, offering compelling arguments for the experimental realization of the detector geometry under investigation.

Abstract

PET remains a cornerstone of molecular imaging,yet the trade-off between spatial resolution,sensitivity,and system versatility persists.While integrating high-resolution inserts into existing systems can enhance performance within a targeted field-of-view,conventional designs lack geometric symmetry in insert-scanner(IS)and insert-insert(II)LORs.This asymmetry necessitates exhaustive,configuration-specific normalization data,severely limiting the mobility and clinical adaptability of the insert.To overcome these limitations,we propose the Adapt-PET(Adaptive-geometry PET)design strategy,which utilizes a "Hardware-Algorithm Co-evolution" approach featuring a movable,DOI-capable insert.The insert geometry is derived by proportionally downscaling the base scanner's transaxial dimensions while maintaining axial consistency,followed by systematic crystal subdivision.This configuration enables a unified geometric mapping strategy that projects IS and II LORs onto a standard scanner-scanner(SS)space.By exploiting intrinsic symmetries,our approach achieves geometric compression ratios comparable to baseline systems,effectively decoupling system normalization from hardware geometry and eliminating the need for re-normalization upon insert relocation.The proposed strategy was validated through GATE simulations of two prototypes integrated with a Siemens Biograph Vision scanner.Positioned at an inner radius of 200-mm,each insert comprised 24 modules of 30×40 subdivided crystal arrays(1.047×0.749×15 mm^3)with a 6-bin,2.5-mm DOI resolution.Evaluations using a uniform cylinder show that the system achieves near-quantitative reconstruction accuracy.Derenzo phantom imaging results reveal that the peak-to-valley ratio can be improved by up to 20%,while torso phantom results demonstrate a substantial enhancement in the detectability of 4-mm lesions.This study establishes a practical framework for flexible,organ-targeted PET imaging through hardware-algorithm synergy.

Abstract

Poor spatial resolution and partial volume effect (PVE) limit PET's ability to accurately quantify radiotracer uptake in small brainstem nuclei such as the locus coeruleus, one of the earliest sites to undergo neuropathological changes in the early stages of tau accumulation associated with Alzheimer's disease. Prism-PET is designed to improve spatial resolution and mitigate the PVE by combining ultrahigh-resolution detector modules with high scanner sensitivity in a practical and cost-effective system.

Latest generation of Prism-PET detector module was evaluated using both qualitative and quantitative performance assessments. The module's flood map was examined to assess crystal separation, pattern stability, and the reliability of crystal identification across the detector module. The tested module produced a clear and stable flood map with well-separated crystal patterns, indicating robust event localization. Quantitatively, we measured the detector's energy resolution, depth-of-interaction (DOI) resolution, and coincidence timing resolution. The tested module achieved 10.34% energy resolution, 3.23 mm FWHM DOI resolution, and 337 ps coincidence timing resolution. In the future work, we will report on the performance of the third generation Prism-PET scanner.

The authors thank the Nuclear Medicine Department of Hospital Clínico San Carlos (Madrid) for support in patient recruitment, image acquisition, and clinical evaluation.

Abstract

Patient motion during PET acquisition is a well-known source of image degradation. In dedicated brain PET systems such as CareMiBrain (Oncovision), patients occasionally slide downward during acquisition despite head immobilization, compromising diagnostic quality in a clinically relevant subset of studies. We present MoDeCo (Motion Detection and Correction), a modified iterative reconstruction algorithm that detects and compensates for intra-acquisition rigid head motion without requiring external tracking hardware. The listmode data are split into temporal fragments; fast preliminary reconstructions are co-registered to the first fragment to estimate rigid transformations, and a modified MLEM/OSEM algorithm applies them within each subiteration to combine the partial back-projections. Head motion was quantified on 256 [18F]FDG patient studies acquired at Hospital Clínico San Carlos (Madrid), and a qualitative clinical comparison was performed on 15 selected studies. Maximum head displacement during acquisition exceeded 5 mm in 14% of patients. In the high-motion subset (n = 10), MoDeCo was rated significantly superior to standard OSEM in 60% of cases and moderately superior in 20%; mild-motion studies (n = 5) were rated as equivalent. No case showed standard reconstruction outperforming MoDeCo. MoDeCo improves image quality in patients with significant motion while preserving equivalence in those without appreciable motion.

Abstract

Photon-counting detectors (PCDs) can perform quantitative imaging by utilizing the differences in the individual energies of X-ray photons, but this analysis requires various corrections, such as charge sharing, to determine the correct attenuation amount. The purpose of this study is to quantitatively clarify the importance of beam hardening and detector response corrections, which can be applied by software processing, when performing imaging with polychromatic X-rays using a line-sensor-type PCD having an anti-coincidence mode. Our PCD was a CdTe detector manufactured by Varex Imaging (pixel size 0.1 mm, thickness 0.75 mm). The response characteristics were calculated using the Monte Carlo simulation code EGS5, and the charge summing effect related to the "anti-coincidence mode" in the four clustered pixels was reproduced in a simple way. The evaluation method involved examining the reproducibility of quantitative values in the effective atomic number (Z_{eff}) images. Simulations using various virtual phantoms and experiments using a non-destructive testing system with the PCD-type line sensor were conducted. As a result, we demonstrated that by including our proposed correction procedure with the anti-coincidence mode, it is possible to generate highly quantitative Z_{eff} images. In conclusion, this study verified that when using PCDs, it is important to implement software-based beam hardening and detector response function corrections in addition to using the anti-coincidence modes.

Abstract

This study evaluated a lead-free $BaSO_4$–silicone composite for diagnostic X-ray shielding (60–100 kVp) using LD-V1 film, combining MCNP6 simulation with experimental validation. Evaluation of a 2 mm thick composite demonstrated shielding efficiencies ranging from 68.79% to 83.50%. Simulated results showed good agreement with experimental measurements, with a maximum deviation of 10.28%. Furthermore, the two-dimensional dose distribution map revealed an average radiation reduction of approximately 60.34% across the material. This result confirms effective attenuation of X-ray radiation across the irradiated field. The dose reduction was also spatially uniform over the entire protected area. In addition, the consistent dose reduction pattern indicates a homogeneous dispersion of $BaSO_4$ particles within the silicone matrix. These findings establish the $BaSO_4$–Si composite as an effective lead-free alternative and demonstrate the utility of LD-V1 film for both quantitative dosimetry and spatial validation in clinical X-ray systems.

Abstract

DXA has evolved beyond standard BMD measurement to include sarcopenia diagnosis and bone quality assessment via the TBS. As TBS is now a recognized modifier in the WHO FRAX Tool , image resolution has become the paramount technical factor determining the performance of DXA systems. This study evaluates the image resolution of iNSiGHT C510 (Osteosys, Korea), the novel DXA model designed for high-resolution whole-body imaging within 3 minutes.

The image resolution of iNSiGHT C510 was quantitatively assessed using a line phantom. The system achieved a vertical resolution of 0.63 lp/mm and a horizontal resolution of 0.9 lp/mm, demonstrating superior resolution capabilities compared to the industry-leading GE Prodigy. Anatomical discriminability was further verified using the spine phantom with increasing BMD levels. Analysis of peak-to-valley ratios, which represent the contrast clarity between bone and intervertebral discs, confirmed that iNSiGHT C510 maintains excellent discriminability despite its longitudinal scan architecture. These quantitative results suggest that the system minimizes ROI setting errors, ensuring high clinical reproducibility for TBS calculations that are highly sensitive to subtle signal variations.This study confirms that iNSiGHT C510 provides image resolution equivalent to global standards. Hardware architecture establishes a technical foundation for reducing identification errors in spinal measurements and improving ROI precision. Consequently, iNSiGHT C510 satisfies the performance requirements demanded by the high-precision sarcopenia diagnostic market. Future work will involve integrating ToF technology to suppress scatter noise inherent in wide fan-beam architectures.

Physics-Guided Retinexformer for Beam Hardening Artifact Correction in Rock CBCT (#1537)

Yuanjue Ma, Liang Li

Tsinghua University, Department of Engineering Physics, Beijing, China

The authors would like to acknowledge Yuanhao Cai and the co-authors of Retinexformer for making their source code publicly available, which significantly facilitated the implementation and development of our proposed architecture.

Abstract

Beam hardening in cone-beam computed tomography (CBCT) of high-density rock causes cupping artifacts and nonlinear CT value deviations, hindering quantitative mineral analysis. Conventional deep learning methods often over-smooth microstructures due to a lack of physical constraints. We propose a physics-informed Retinexformer framework that reformulates the polychromatic X-ray degradation as a multiplicative Retinex model. Under this paradigm, the non-uniform hardening field is treated as a degraded illumination map, while the pristine rock structure represents the ideal reflectance. A pre-trained Denoising Diffusion Implicit Model (DDIM), combined with mask-guided moment matching, is utilized to explicitly generate a statistically aligned physical hardening field prior. Furthermore, a multi-scale feature encoder extracts high-frequency structural details from the residuals between the input and the prior to guide the denoising process. Experiments on a 10-cm diameter underground rock dataset show that our method significantly corrects CT value deviations while preserving the fine structure. Quantitatively, it achieves a PSNR of 37.13 dB and an SSIM of 0.940, reducing RMSE to 0.0149—significantly outperforming SOTA baselines (NAFNet, Retinexformer, MambaIRv2). Notably, our model achieves this with only 2.00M parameters and 19.42G FLOPs, offering a highly efficient and interpretable solution for CT artifacts correction in dense media.

Mitigating Scatter-Induced BMD Errors in Wide Fan-Beam DXA Using Anti-Scatter Grids (#2260)

Myungwoo Oh, Youngbok Ahn, Sunghyun Min, Hyuntae Leem, Chanwoo Kwon

Osteosys Corp., R&D Center, seoul, South Korea

This research was financially supported by the Ministry of Trade, Industry and Resource (MOTIR), Korea, under the “Global Industrial Technology Cooperation Center (GITCC) program” supervised by the Korea Institute for Advancement of Technology (KIAT) (Task No. P0030253).

Abstract

Dual-energy X-ray absorptiometry (DXA) is the clinical standard for bone mineral density (BMD) assessment. Modern wide fan-beam DXA architectures (fan angle ≥ 20°) shorten whole-body acquisition to under three minutes but enlarge the irradiated volume, raising the scatter-to-primary ratio with field size. Conventional DXA omits anti-scatter grids, relying on the long object-to-image-detector distance (OID > 580 mm) for scatter rejection via the air-gap effect. Whether this assumption holds for wide fan-beam DXA has not been directly tested. We investigated residual scatter in an experimental wide fan-beam DXA system using three complementary experiments on step-wedge and anthropomorphic phantoms. First, we implemented an outer-channel scatter probe and detected measurable scatter at outer channels even at OID > 580 mm. Second, with an 8:1 anti-scatter grid we quantified the dual-energy mass attenuation difference Δ(μ/ρ); at the maximum phantom configuration (25 cm polycarbonate + 4.9 cm aluminum), scatter caused an inversion of Δ(μ/ρ) in the no-grid configuration (−0.018 cm²/g); the 8:1 grid restored Δ(μ/ρ) to 0.076 cm²/g — a partial recovery only. Third, a 14:1 grid successfully suppressed the spurious BMD elevation. Compared to the no-grid baseline which showed a severe thickness-dependent BMD bias (coefficient of variation of approximately 19%), the 14:1 grid reduced the variability to 3% across 0–140 mm of added polycarbonate layers. These findings establish that explicit scatter compensation — whether through anti-scatter grids or software-based correction — is essential for thick-patient measurements at wide fan-beam DXA.

[1] Institute of High Energy Physics, Beijing Engineering Research Center of Radiographic Techniques and Equipment, Beijing, China; [2] University of Chinese Academy of Sciences, School of Nuclear Science and Technology, Beijing, China

Abstract

Contrast agents play an important role in spectral CT because they enhance the visibility of vessels, organs, tumors, and lesions, thereby improving image interpretation and lesion identification. However, accurately quantitative contrast-agent decomposition remains challenging. Conventional material decomposition algorithms still suffer from limited quantitative accuracy even in contrast-agent imaging. This problem becomes more severe when multiple contrast agents coexist. To address this limitation, we propose an empirical multi-agent decomposition method. The proposed method first applies conventional empirical decomposition to obtain initial decomposition results and estimate the corresponding decomposition errors. Then, bivariate error surfaces are constructed to model the relationship between iodine and gadolinium concentrations and their decomposition errors. These fitted error surfaces are subsequently used to compensate for the errors produced by conventional empirical decomposition. Simulated experiments demonstrate that the proposed method can simultaneously decompose iodine and gadolinium with improved quantitative accuracy, and the global MAPE and NRMSE are effectively reduced compared with the image-domain decomposition method for the test phantoms.

Empirical Correction of Detector Response for Quantitative X-Ray Transmission Modelling and its Application to Computed Tomography

(#2574)

Qingxiang Chen, Ben James, Yi Liu

The Commonwealth Scientific and Industrial Research Organisation, Mineral Resources, Lucas Heights, Australia

Abstract

X-ray computed tomography (CT) relies fundamentally on accurate transmission measurements to reconstruct meaningful attenuation maps. However, detector response non-linearity systematically biases transmission measurements away from the values predicted by the polychromatic forward model, propagating these errors into reconstructed data. To address this, a combined spectral modelling and empirical calibration framework was developed for a high-resolution flat-panel detector, enabling prediction of measured transmission values across a broad range of sample thicknesses and compositions. A polychromatic spectral model was constructed by combining tube-spectrum estimates with Beer–Lambert attenuation using NIST/XCOM coefficients, convolved with an effective CsI scintillator response function. Predicted transmission values were compared against experimental measurements obtained using high purity elemental foils spanning a wide range of thicknesses. Consistent and reproducible discrepancies between modelled and measured values revealed a structured detector response non-linearity not captured by the forward model. A first-order empirical correction was derived from the model–experiment residuals, yielding a fitted detector-response exponent of $\alpha = 1.47$ applied to model predictions to reproduce experimental detector behaviour. The calibrated model can therefore generate realistic transmission values consistent with measured detector output across a range of sample configurations. These findings highlight the broader potential of this framework, particularly for dual-energy CT, where material decomposition relies critically on the relative contrast between acquisitions at different tube voltages. A calibrated forward model of this kind offers a pathway toward improved relative CT threshold accuracy, supporting more reliable separation of materials with overlapping attenuation properties and more robust quantitative interpretation of reconstructed data.

Abstract

This paper develops a pipeline for generating synthetic cone-beam computed tomography (CBCT) projections from real dental CBCT acquisitions, providing a reference for supervised learning. To this end, we segment and synthesize fine structures from real CBCT acquisitions to obtain a material map of the head volume. Using the characteristics of the CBCT scanner, notably the effective spectrum, we simulate the acquisitions by modeling a polychromatic X-ray source and adding compound Poisson noise. The results demonstrate the realism of the generated synthetic CBCT acquisitions, as well as the plausibility of the simulated artifacts.

Image Quality Evaluation of Cone Beam Computed Tomography (CBCT) in an O-arm Fluoroscopy Machine Using the SedentexCT IQ Phantom (#2974)

John Patrick Ryan S. De Guzman[1,2], Agnette Peralta[2]

[1] Philippine General Hospital, Department of Radiology, Manila, Philippines; [2] University of Santo Tomas, The Graduate School, Manila, Philippines

The accomplishment of this research was attained because of the wonderful people who have contributed, showed support, and served as inspiration to this research and the researcher. I would like to express my sincere gratitude to my advisers, Ms. Agnette P. Peralta and Ms. Melanie Marquez. Ma'am Agnette's admirable dedication to medical physics was an inspiration to contribute and make advancements in knowledge for the medical physics community in the Philippines. I am thankful for the endless support of Ma'am Melanie; she gave me the opportunity to progress with this research. Her uplifting and joyful personality always gave me hope and perseverance in finishing this research.

Abstract

The O-arm fluoroscopy machine, an application of cone beam computed tomography (CBCT) for interventional procedures, lacks a dedicated image quality (IQ) phantom for system image performance evaluation. This study aimed to investigate the viability and limitations of using the SedentexCT IQ phantom, a phantom originally designed for dental CBCT, to assess the image quality of resultant CBCT images of an interventional O-arm unit. Six CBCT image quality tests were performed (i.e. Uniformity, Image Noise, Geometric Accuracy, Voxel Intensity Values, Contrast Resolution, and Spatial Resolution), and corresponding parameters were assessed as baseline data in the low dose, standard dose, high dose, and enhanced cranial modes of the O-arm machine. The procedures were structured to the EFOMP-ESTRO-IAEA CBCT quality control protocol. An observed limitation of the phantom was the evaluation of the spatial resolution (lp/mm), since the lowest resolution of the SedentexCT IQ phantom is 1.0 lp/mm. Overall, since the phantom was applicable for the required CBCT image quality tests, the SedentexCT IQ phantom can be considered as a viable tool for image quality testing of the O-arm machine.

Validation of conventional mammography material decomposition using VICTRE simulated breast data (#3018)

John Paul Phillips, Emil Sidky, Ingrid Reiser, Zheng Zhang, Kirti Kulkarni, Xiaochuan Pan

The University of Chicago, Department of Radiology, Chicago, USA

This research was supported in part by the National Institut of Biomedical Imaging and Bioengineering of the National Institutes of Health under award numbers R01CA287302.

Abstract

The purpose of this work is to validate basis material decomposition in breast cancer screening mammography using a conventional single-kV scan. We employ mammography system physics modeling and a pathlength constraint to enable estimation of the basis material images. Using 3D breast phantoms and low noise Monte Carlo projection data generated with the FDA VICTRE software, we decompose transmission data into pathlength basis images of adipose and glandular tissue. The decomposition recovered adipose and glandular maps with mean absolute errors of 3.47 mm and 1.83 mm respectively. Accuracy along the skinline and nipple is degraded due to material mismatch. The results indicate material decomposition in mammography using a single energy acquisition is feasible to enable the quantitative recovery of adipose and glandular material maps.

Development of a 64-Channel Energy and Timing Acquisition System for TOF-DXA (#3146)

Sang-Hyun Chun, Jiwoong Jung, Jiwon Nam, Sena Kwon, Jin Ho Jung, Yong Choi

Sogang University, Department of Electronic Engineering, Intelligent Signal Processing System (ISPS) Laboratory, Seoul, South Korea

This research was supported by the Industrial Technology Innovation Program funded by the Ministry of Trade, Industry and Energy (no. P0030253), by the Korea Medical Device Development Foundation Grant funded by the Ministry of Science and ICT, the Ministry of Trade, Industry and Resources, the Ministry of Health & Welfare, the Ministry of Food and Drug Safety (no. 2410019162, no. RS-2026-25540876), and by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (no. RS-2026-25565373) of the Republic of Korea.

Abstract

Time-of-flight dual-energy X-ray absorptiometry (TOF-DXA) is proposed as a method for enhancing material decomposition by incorporating timing information into conventional dual-energy attenuation measurements. In this study, a 64-channel energy and timing acquisition system was developed for TOF-DXA.

The detector consisted of a 64-channel LYSO array with a pixel size of 3 × 3 × 3 mm³, coupled to four 16-channel Broadcom NUV-MT SiPM arrays. Detector signals were split into independent energy and timing paths. For the energy path, signals were processed through differential amplifiers and digitized using 10-bit multichannel analog-to-digital converters. Timing signals were processed using front-end comparators and a Kintex-7 FPGA-based tapped delay line (TDL) time-to-digital converter. The TDL was implemented using a single-chain architecture based on CARRY4 primitives.

This dual-path configuration enabled synchronized acquisition of energy and timing information on an event-by-event basis. The FPGA logic measured energy values through peak detection and synchronized them with timing data stored in a timing FIFO to ensure event-by-event alignment. The energy resolution was evaluated using a Co-57 source at 122 keV, while the timing resolution was evaluated in coincidence with a reference detector using a

Na-22 source. X-ray spectra were acquired using an X-ray generator operated at 83 kVp and 0.2 mA with a Ce filter (K-edge: 40.4 keV) to evaluate system performance in the DEXA energy range.
The energy resolution was 16.3% at 122 keV, and the coincidence timing resolution was 104 ps at 511 keV. The low- and high-energy peaks were clearly resolved in the acquired X-ray spectrum.
These results demonstrated that the developed 64-channel acquisition system could simultaneously measure energy and timing information for TOF-DXA. Optimization of the acquisition board is currently in progress, and comprehensive system performance results will be presented at the conference.

Abstract
Static computed tomography (SCT) enables fast, task-specific imaging through ultrafast and flexible firing among distributed focal spots. However, it introduces irregular and incomplete data acquisition, which poses great challenges to reconstruction. In this work, we propose Geometry-Aware Reconstruction Method (GARM) for SCT across diverse scanning strategies. The Geometry-Guided Dimension Reduction (G2DR) Network first transforms irregular 3D projections into slice-wise 2D fan-beam projections using geometric information derived from ray positions. A 2D dual-domain network then suppresses sparse-view artifacts guided by geometric and Radon-space information. Simulated experiments demonstrate that GARM achieves high-quality reconstruction from irregular and incomplete projections with strong generalization capability across diverse scan strategies.

This work was supported by the European Research Council Starting Grant #101041972 and by the ATRAE grant #ATR2023-143812 from the Spanish Research Agency.

Abstract

Compton cameras are imaging systems that detect Compton-scattered gamma rays using two position-sensitive detectors, typically called the scatterer and the absorber.

Each interaction pair defines a Compton cone enabling three-dimensional image reconstruction.

In this work, we investigate how the selection of low scattering angle events influences image quality.

A GATE-based simulation of a Si/CdTe Compton camera system was developed to generate Compton cone data.

A 511 keV rod phantom with source cylinders of radii from 1.5 mm to 0.75 mm was implemented, and 100 M primary photons were simulated.

Images were reconstructed from subsets obtained by applying a maximum threshold on Compton electron energy in the scatterer.

Energy selections of 5, 10, and 15 keV (corresponding to scattering angles of 8°, 11.4°, and 14°) were used, along with a reference dataset without any energy cut for standard CC reconstruction comparison.

We show that for two rods of 1.5 mm and 1.25 mm radius, the peak-to-valley ratio (PVR) without any energy selection is approximately 3.5. By selecting energy deposits below 15 keV (14°) the PVR nearly triples, with further improvements observed for lower energy thresholds, reaching a value of 13.8 for a 5 keV energy cut

For smaller rod radii, the PVR remains below 3, although low-energy event selection still yields enhancements of approximately 60%, 30%, and 17% for radii of 1 mm, 0.75 mm, and 0.51 mm, respectively.

These findings support event-selection strategies for CC systems capable of triggering at low energies in the scatterer.

Restricting to the most informative events can reduce computational load and improve reconstruction performance, with the strongest benefits observed for rods with radii above 1 mm.

Abstract

Dual-view SPECT planar imaging is a widely used method in clinical bone scan screening due to its efficiency and low radiation dose compared to whole-body SPECT/CT imaging. However, its diagnostic efficacy is often limited by anatomical overlap and the absence of depth information. Achieving high-quality 3D image from only two projections remains a challenge for traditional methods. Furthermore, existing deep learning-based approaches for ultra-sparse-view SPECT reconstruction are mainly designed for cardiac imaging and cannot be directly adapted to bone scintigraphy. To address these limitations, we propose a deep learning framework for 3D SPECT reconstruction from orthogonal biplanar projections and CT Scout views. The framework comprises a 3D condition map generation module and a structure-guided 2D conditional diffusion module, facilitating a two-stage reconstruction process including an initial coarse reconstruction followed by iterative refinement via a diffusion model. Quantitative results demonstrate that the proposed method achieves better recovery coefficients for bone tissues and metastatic lesions, as well as improved LPIPS scores for perceptual quality. Qualitative assessments further reveal that the reconstructed images exhibit highly realistic textures and shows strong agreement with standard full-view scans. This method provides a fast, low-radiation 3D reconstruction strategy with considerable potential to optimize clinical bone scan workflows, enhance diagnostic accuracy and improve patient comfort.

This work was supported in part by the German Research Foundation (DFG) by Grant No. 51 658 7313 (PROSIT).

Abstract

Reconstructing the emission distribution of prompt gamma radiation in time and space offers a unique advantage: it reveals the primary particle motion inside the irradiation target during particle therapy. Similar to typical tomographic emission reconstruction scenarios, the measurement process based on Prompt Gamma Timing can be described by a linear system model and Poisson-distributed measurement data. However, the structure of the emission domain (emission time and position of the prompt gammas) and the detection domain (detector index and event time difference relative to a primary particle signal) are unique. In this work, we inspect some features of this inverse problem and analyze related fundamental limitations based on reconstructions with ideal data and the singular value decomposition of the system matrix. The results show a need for regularization and help identify possible improvements to the approach. Additionally, understanding this inverse problem in-depth also supports the development of other Prompt-Gamma-Timing-based techniques.

Abstract

The Software for Tomographic Image Reconstruction (STIR) is a long-standing open-source platform for PET and SPECT reconstruction that has supported tomographic imaging research for more than two decades. Public STIR documentation dates to the early 2000s, and the project remains actively developed, with a current public release in November 2025 and a GitHub repository reporting 9,409 commits, 146 stars, and 108 forks. Recently there have been major contributions, that have expanded substantially the framework in scanner support, motion correction, and raw-data interoperability. Advances include support for the Siemens Biograph Vision Quadra long axial field-of-view PET/CT system, a data-driven rigid head motion-correction workflow for brain PET, and PETSIRD as a vendor-independent raw-data interface. Here, we demonstrate the impact of motion on clinically relevant quantitative measures. Together, these developments reinforce STIR's position as a mature, community-driven platform for modern PET reconstruction research.

Developments in fabrication and design flexibility of amorphous silicon microchannel plates (#2584)

Georgios Konstantinou, Loris Barraud, Christophe Baillif, Nicolas Wyrsch

EPFL, Neuchatel, Switzerland

The project is funded by the SNF SPARK grant no CRSK-2_237272

Abstract

The technology of amorphous silicon-based micro-channel plates (AMCPs) uses a versatile approach to stack hydrogenated amorphous silicon in thicknesses up to 100 µm, using plasma-enhanced chemical vapor deposition (PECVD) and etch microchannels of diameter below 2 µm every 5 µm, on a hexagonal pattern, by deep reactive ion etching. With gains up to 1000 for reverse bias less than 300 V, the design is possible to build on arrays of sensitive transimpedance amplifiers, integrated in read-out circuits with high channel density, such as for instance 15 by 15 µm. This ensures single photon detection with quantum efficiency up to 30% and noise rates below 50 Hz/cm², if combined with state of the art photocathodes such as the hi-QE from Photonis. Current fabrication runs focus on direct integration of the stack on ASICs, to be integrated with the photocathode over the next months. Measurements show timing response with jitter below 10 ps, making this high-precision photodetector ideal for radiation detectors combining ultra-fast photon emission and low light yield, such as Cherenkov.

Abstract

This paper presents a universal calibration method based on spatial vector decomposition to address the challenge of dynamically changing and difficult-to-calibrate geometric parameters in cone-beam computed tomography (CT) systems with complex scanning trajectories. The proposed method enables high-precision and robust calibration for a broad range of CT imaging systems. First, the projection matrix at each scanning angle is computed using a calibration phantom. This matrix is then decomposed into spatial vectors representing the system's geometric state, including the position of the X-ray source, the detector reference point, and orientation vectors. These vectors can be directly used for image reconstruction or converted into device-specific parameters. A vector-based detector mapping algorithm is also introduced to facilitate efficient projection data correction. Experiments on Micro-CT, CL and robotic-arm CT systems confirm that the method significantly improves image clarity, suppresses artifacts and distortions, and accurately reconstructs the actual motion trajectories of the X-ray source and detector. The method demonstrates high accuracy and versatility, providing a reliable calibration solution for high-degree-of-freedom CT systems.

Abstract

CT-less attenuation correction in PET has gained increasing interest as a means to reduce patient radiation exposure, with recent AI-based methods providing anatomically plausible attenuation estimates from emission data and complementary inputs. However, residual inaccuracies in such attenuation maps can still impact PET quantification.

Joint estimation of activity and attenuation provides a physics-based framework to mitigate these effects, but remains less well constrained in the absence of time-of-flight (TOF) information.

This work evaluates the use of AI-generated CT-less attenuation maps as spatial priors for joint estimation of activity and attenuation in TOF and non-TOF PET. Using a maximum-a-posteriori formulation, the CT-less attenuation map is employed both as an initial estimate and as a regularising prior.

Experiments on paediatric PET datasets show that this approach stabilises joint reconstruction and recovers anatomically plausible attenuation maps, including in the non-TOF case. These results support the use of CT-less attenuation maps as effective priors for robust PET reconstruction.

Abstract

Dual-panel positron emission tomography (PET) scanners offer compact, cost-effective, and organ-dedicated imaging geometries, but their limited angular coverage introduces anisotropic resolution loss and elongation artifacts. This work presents a convergence-informed artificial intelligence (AI)-guided iterative reconstruction framework for the ProVision dual-panel PET system. The proposed approach exploits voxel-wise convergence information (VCI) extracted from the first 15 iterations of list-mode multi-ray maximum likelihood expectation maximization (MLEM) reconstruction. VCI was incorporated into five reconstruction strategies: analytic VCI-guided MLEM, multilayer perceptron-based VCI-guided MLEM, standalone 3D Swin-UNet reconstruction, AI-guided maximum a posteriori reconstruction (AI-MAP), and AI-initialized MLEM (AI-MLEM). Training and evaluation were performed using Monte Carlo simulations, a scaled NEMA image quality phantom, an external simulated patient test set, and an experimental anthropomorphic pelvis phantom. Compared with conventional MLEM, the proposed hybrid methods substantially improved contrast recovery, background uniformity, and geometric fidelity. AI-MLEM increased the contrast recovery coefficient from 53.16% to 82.35%, reduced background variability from 12.38% to 8.25%, and reduced the elongation ratio from 1.48 to 1.15. On the external simulated patient test set, AI-MLEM improved structural similarity from 0.446 to 0.816 and reduced normalized mean absolute error from 0.405 to 0.215. Experimental phantom results further confirmed improved lesion conspicuity and reduced vertical spreading. These results demonstrate that early-iteration convergence behavior provides useful voxel-wise guidance for mitigating limited-angle artifacts while preserving data consistency in dual-panel PET reconstruction.

Abstract

We propose a continuous Gaussian representation for PET reconstruction, modeling the activity distribution with normalized Gaussian basis functions. This reformulates PET reconstruction as a compact differentiable optimization problem by coupling an analytical Gaussian forward model with Poisson likelihood. The key component is an anatomically guided adaptive density control strategy, which dynamically prunes, splits, and clones Gaussian primitives according to contribution, gradient, and MRI-derived mask constraints, thereby allocating representation capacity to informative regions while suppressing redundant components. Image-domain Huber-TV regularization is incorporated to stabilize reconstruction. Experiments on 2D simulations demonstrate competitive performance across count levels and clear advantages under low-count conditions, suggesting the potential of adaptive continuous representations for PET reconstruction.

Abstract

The latest generation of simultaneous positron emission tomography and magnetic resonance imaging (PET/MRI) scanners is now at the forefront of hybrid imaging. As of now, the reconstruction of both modalities is independent, but research is ongoing in MRI-guided (MRIg) PET reconstruction, where information from the MRI is used as prior information in the iterative PET reconstruction.

We present three different clinical cohorts: meningioma patients (n=8) scanned with [^{68}Ga]DOTATOC, a single pituitary adenoma scanned dynamically with [^{18}F]FET and a neurodegenerative cohort (n=10) scanned with [^{18}F]FDG. The cohorts have been analyzed with standard OSEM reconstruction (b=0) versus MRIg reconstruction. The meningioma cohort showed an increased volume with standardized uptake values (SUV) above 2.5 when using MRIg reconstruction, and an increased SUV_{max} in the tumor. The pituitary adenoma showed increase time-activity curve both for β=1 and β=2. The neurodegenerative cohort showed stable SUV ratios of the cerebral-to-cerebellar cortex down to 3 minutes.

This preliminary work shows the clinical value in utilizing the information from the MRI in PET reconstruction with applications both to increase image quality and resolution, but also to facilitate faster imaging.

A Hybrid Neural Network Model for DaTscan Diagnosis of Neurodegenerative Disorders (#2498)

Efstratios Roupas[1], Aikaterini Koukopoulou[1], Eleni Mitsou[1], Efstathios Stiliaris[2]

[1] National and Kapodistrian University of Athens, Medical School, Athens, Greece; [2] National and Kapodistrian University of Athens, Department of Physics, Athens, Greece

Abstract

This study presents the development of a hybrid Neural Network designed to simultaneously reconstruct medical images from their sinograms and to predict diagnostic parameters for neurodegenerative disorders, specifically Parkinson's disease. The training pipeline utilizes simulated Dopamine Transporter Scan (DaTscan) brain images and their corresponding sinograms, generated via a custom Monte Carlo based framework that employs analytically driven functions to model realistic hotspot and background noise characteristics. The architecture integrates image reconstruction and disease-specific parameter estimation into a unified framework. Key diagnostic features include the bilateral asymmetry of radiotracer uptake within the caudate nuclei; deviations in spatial distribution or intensity within predefined Regions of Interest (RoIs) serve as primary indicators of neuropathology. This dual-function approach advances automated, AI-assisted functional neuroimaging, offering a robust pathway for early, non-invasive diagnosis of neurodegenerative conditions.

Abstract

Limited-angle computed tomography (LACT) reconstruction is highly ill-posed because missing projection views lead to severe artifacts and incomplete boundaries. This work proposes a global-local latent diffusion framework for limited-angle CT reconstruction. The proposed method performs diffusion reconstruction in the latent space of a variational autoencoder and jointly incorporates U-Net-based local modeling and transformer-based global modeling into the denoising process. The U-Net component captures multiscale spatial details and boundary continuity, whereas the transformer component models long-range dependencies and global structural relationships associated with missing-angle information. These complementary priors are adaptively integrated to guide latent-space denoising. During sampling, a physics-guided data-consistency constraint is further introduced. Specifically, the intermediate latent prediction produced by the model is decoded back to the image domain, processed with a projection-consistency operation, and then re-encoded into the latent diffusion trajectory. Preliminary experiments on a simulated data set show favorable reconstruction quality, indicating that the proposed global-local diffusion framework can improve structural fidelity and projection consistency for limited-angle CT reconstruction.

Abstract

Proton CT is a promising alternative to X-ray CT for proton therapy treatment planning, allowing direct estimation of the relative stopping power map within the patient body without relying on conversion from Hounsfield units. Conventional list-mode proton CT scanners measure the energy loss of each individual proton to estimate the integral of the relative stopping power along its path, the water-equivalent path length, but do not meet the requirements for clinical use due to their low acquisition rates. An alternative proton CT scanner design was recently proposed where the time-of-flight of each proton is measured between two detectors located before and after the patient along the proton beam. The main advantages of this sandwich time-of-flight design are its compactness and high acquisition rates. However, conversion from sandwich time-of-flight data to water-equivalent path length is not possible. In this work, we propose an iterative reconstruction of the sought relative stopping power map based on the non-linear forward problem. The method is assessed using Monte Carlo simulations of the acquisition of four simple phantoms. Although computationally expensive, this method accurately recovers the relative stopping power map.

Abstract

A high-sensitivity, high-resolution brain PET system with a multi-resolution detector design has been developed. However, image reconstruction without normalization correction produces pronounced image artifacts. In this study, we implemented list-mode reconstruction with direct normalization correction using normalization factors derived from simulation data for this multi-resolution PET system. The effect of normalization correction on reconstructed image quality was evaluated using Monte Carlo simulations and real scan data from a modified image-quality phantom. The results showed that normalization-corrected reconstruction substantially reduced image artifacts and improved image uniformity in simulated data, while residual nonuniformity remained in real scan data due to the lack of experimentally measured crystal efficiencies. Overall, this work demonstrates the feasibility of normalization correction for the dual-layer brain PET system and provides a basis for further experimental normalization using measured crystal efficiencies

Abstract

In low-dose (LD) myocardial perfusion imaging (MPI) with single-photon emission computed tomography (SPECT), radiation exposure is reduced at the expense of image quality, potentially impairing perfusion defect detection. Deep learning methods have shown promise in reducing noise in LD MPI images. However, clinical data exhibit varying cardiac orientations, increasing the complexity of the learning task for denoising models. We hypothesize that standardizing cardiac orientation with respect to a common reference prior to training can reduce this complexity and improve denoising performance. We evaluated this approach with a previously proposed edge-aware convolutional autoencoder (EdgeCAE) across four levels of trade-off between edge preservation and mean-squared error (MSE) fidelity. The model was trained on 738 clinical subjects and tested on 300 noise realizations derived from two independent patient anatomies, with and without pre-reorientation. Our results demonstrated that cardiac reorientation consistently reduced the MSE compared to the full-dose reference images. This was also supported by visual assessment on an independent patient cohort.

Computation work has been carried out on the high-performance computing platform supported by the Center for Computational Research at the University at Buffalo.

Abstract

Multiplexing in SPECT renders the measurement operator underdetermined. In symmetric multi-source configurations, iterative ambiguity reinforcement sustains persistent ghost artifacts. Established mitigation strategies require supplemental single-beam nonmultiplexed projections, constraining collimator design and sacrificing sensitivity. Sparsity in gradients for common tracer distributions motivate total-variation (TV) regularization as a natural demultiplexing strategy: ghost artifacts produce extra gradient support that TV prior penalizes, breaking the ambiguity cycle. We demonstrate that MAP-TV (maximum a posteriori total variation) acts as an active reconstruction-stage demultiplexer, a supplemental approach to modifying the projection set in the data acquisition stage.

Abstract

In this paper, we propose a new projection method for PET, called Monte Carlo Point Projectors (MCPP), which back-projects measured gamma interactions in the detector by sampling potential positions of the event source within the field of view (FoV). We apply this method to scattered events using a projector for scattered lines of response (ScLoR), as well as a combination of scattered lines of response and Compton cones of response (CoR). The simulated system is a cylinder with a radius of 15~cm and a length of 16~cm, composed of 12 Cadmium Zinc Telluride panels, with a 7~cm radius water sphere at the center to simulate in-patient scatter. We show that for this system, the point spread function (PSF) resolutions were 8.3~cm for CoR and 5.3--4.7~cm for the proposed ScLoR projector and the combination with the CoR, demonstrating the advantage of using scattered events with the MCPP method. We also studied how the missing energy of scattered events influences the PSFs obtained with MCPP, noting that lower missing energy yields better resolution. Its combination with a scatter classification method on experimental data is being evaluated. In conclusion, the MCPP approach facilitates the integration of different projectors to process a maximum of detected events.

Abstract

Dynamic PET imaging is becoming increasingly valuable in neuroimaging and cardiac imaging, thanks to its ability to track functional changes over time.

Conventional approaches to dynamic PET imaging need to find a balance between frame duration and noise: shorter temporal frames can provide important information on rapid physiological processes, but at the expense of increased noise. Traditional filtering strategies aim at reducing noise, but inherently cause loss of spatial and/or temporal resolution.

In this work, we represent dynamic PET images using a subspace model during image reconstruction to substantially reduce noise while preserving spatial and temporal information, thereby exploiting the spatiotemporal correlations in dynamic images. We demonstrate the power of the proposed approach on an in-vivo scan of a nonhuman primate performed on the high-sensitivity, high-resolution NeuroEXPLORER scanner. Dynamic images reconstructed at 1-second frames exhibit high resolution and dramatically reduced noise compared to conventional reconstructions, enabling the visualization of early tracer perfusion, respiratory motion and contrast changes in the whole body, without any gating. The proposed method shows promise for short-frame imaging of the brain and body.

Abstract

Dynamic ^{99m}Tc-diethylenetriaminepentaacetic acid (DTPA) planar renography is widely used for quantitative renal function assessment, but Gates-based glomerular filtration rate (GFR) estimation depends on manually defined kidney and background regions of interest (ROIs), which is time-consuming and operator-dependent. We developed RFVGG, an ROI-free hierarchical deep learning framework that learns directly from dynamic renography image sequences using routinely available Gates-derived labels. This retrospective study included 728 consecutive patients who underwent dynamic ^{99m}Tc-DTPA planar renography. RFVGG was built on a shared 3D VGG-style backbone with hierarchical task-specific heads for three-, five-, and six-category GFR stratification. Model development followed five-fold cross-validation, and RFVGG was compared with CNN, ResNet-18, and DenseNet under identical evaluation settings. Classification performance was evaluated using accuracy, precision, recall, and specificity. RFVGG achieved accuracies of 0.842±0.020, 0.705±0.043, and 0.606±0.042 for the three-, five-, and six-category tasks, respectively. The corresponding precisions were 0.846±0.017, 0.668±0.037, and 0.614±0.034; recalls were 0.843±0.024, 0.689±0.045, and 0.642±0.039; and specificities were 0.915±0.012, 0.920±0.012, and 0.920±0.008, respectively. These results indicate that RFVGG can perform automated ROI-free GFR category stratification from dynamic ^{99m}Tc-DTPA planar renography without contour-based kidney or background ROI tracing

Abstract
Quantitative brain PET studies often require arterial input functions (AIF), which can be derived from radiotracer concentrations through the internal carotid arteries (ICAs) in dynamic PET images. Image-derived input function (IDIF) methods avoid invasiveness; however, challenges in precise quantification of dynamic flow conditions and correction of partial volume effects (PVE) persist. Recently developed dedicated PET systems for brain imaging, such as the RETIMAGER System, offer excellent spatial and temporal resolution, which is of high relevance for IDIF determination. In addition, hybrid systems offer complementary information for improved IDIF validation. This study shows the design and development of digital and physical phantoms for future validation of IDIF methods in Brain PET systems. A two-phase approach employs the design and construction of a cylindrical phantom with an ICA insert matching real structural geometries. Phase 1 uses a digitalized phantom with Monte Carlo (MC) simulations to validate and optimize acquisition and reconstruction parameters. Phase 2 is in progress for experimental versus simulation validations using a physical phantom with an ICA insert to simulate flow dynamics using an injector. Additionally, a 3D head phantom incorporating gray matter (GM), white matter (WM), scalp, and ICA structures has been designed and is in fabrication for future comprehensive validation.

TRACE: A New Phantom for Simultaneous Multi-Method Assessment of PET Spatial Resolution (#2135)

Deepa Choudhary[1,2], Brahim Mehadji[1], Ramsey D. Badawi[1], Negar Omidvari[1], Benjamin A. Spencer[1]

[1] UC Davis Health, Radiology, Sacramento, USA; [2] UC Davis, Biomedical Engineering, Davis, USA

Abstract
Spatial resolution assessment in positron emission tomography (PET) typically relies on the full-width at half-maximum (FWHM) of point-like line sources reconstructed with filtered back-projection (FBP), yet modern clinical imaging predominantly uses iterative reconstruction methods, motivating the need for phantoms that evaluate resolution under clinically relevant protocols. To address this, we present TRACE (Tapered Rod Array for Continuous-resolution Evaluation), a 3D-printed phantom enabling simultaneous spatial resolution assessment via four complementary methods – FBP FWHM, modulation transfer function (MTF), Rayleigh criterion, and visual assessment – in a single acquisition. TRACE consists of a tapered cone with continuously decreasing fillable conical rod diameters (4.8–1.2 mm over 10 cm) and three integrated capillary slots for NEMA-compatible line

source measurements. The phantom was scanned on the uEXPLORER total-body PET scanner in transverse (XY) and axial (XZ) orientations. FBP FWHM yielded mean transverse resolutions of 3.0 ± 0.2 mm (radial) and 3.4 ± 0.2 mm (tangential), and 2.9 ± 0.5 mm axially. Under OSEM reconstruction, the Rayleigh criterion and visual assessment resolved rods down to 1.8 mm (XY) and 2.0 mm (XZ), while the 50% and 10% MTF were achieved at 2.8 mm and 1.6 mm (XY), and 2.6 mm and 1.7 mm (XZ), respectively. TRACE bridges standardized and clinically relevant resolution assessment, delivering all four metrics in a single acquisition and offering a comprehensive framework for PET spatial resolution characterization

Abstract
Conventional methods for assessing PET spatial resolution, such as the NEMA NU-2 protocol and ACR guidelines, provide limited insight into the effective resolution achieved with modern clinical reconstruction techniques. In this work, we propose a simple and low-cost fan-pattern paper phantom enabling modulation transfer function (MTF)-based analysis for continuous spatial resolution characterization. The phantom consists of laser-cut paper in a fan geometry with gap sizes decreasing from 5 mm to 1 mm which is briefly immersed in an F-18 solution. Reproducibility and repeatability were evaluated on a uEXPLORER PET/CT system. Images were reconstructed using filtered back projection (FBP) and multiple clinical reconstruction algorithms, including OSEM and artificial intelligence (AI)-based methods. Spatial resolution full width at half maximum (FWHM) was derived from the MTF using the 50% frequency criterion. Results demonstrate an average radial resolution of 3.23 ± 0.034 mm for reproducibility and 3.22 ± 0.054 mm for repeatability, consistent with NEMA NU-2 measurements but with lower uncertainties, which can be attributed to the robustness of the MTF evaluation method. The proposed approach enables rapid (<5 min), robust, and continuous assessment of spatial resolution, including under clinical and AI-based reconstruction conditions. The proposed phantom provides a practical tool for PET system characterization and reconstruction optimization and will be made available to facilitate wider adoption.

Abstract

Lutetium-177, a combined gamma and beta emitter, is gaining significant attention as a theranostic isotope with clinical applications in metastatic prostate cancer and neuroendocrine tumors. Quantitative imaging of ^{177}Lu in a preclinical setting is important for therapy optimization. This study evaluates the image quality performance of a small-animal SPECT scanner equipped with an ultra-high-sensitivity collimator for ^{177}Lu using a SPECT IQ phantom adapted from the NEMA NU 4 PET phantom. Whole-body acquisitions were performed using a multi-bed protocol, and projection data were reconstructed with an iterative algorithm under different post-filtering conditions. Image quality was assessed using recovery coefficients (RCs) for rods of varying diameters, and image noise was quantified as the percentage standard deviation (%STDunif) within a uniform region. The results show that RC varies with rod size, iteration number, and post-reconstruction filtering. Effective recovery was observed for 1.35 mm rods (RC ~0.77), while RC values decreased to approximately 0.38 and 0.23 for 1.15 mm and 0.95 mm rods, respectively, indicating that reliable recovery is achieved for rod sizes of about 1.5 mm. Image noise increases with iteration number and decreases with stronger smoothing, reflecting the expected resolution–noise trade-off. These initialfindings demonstrate the capability of the SPECT IQ phantom for quantitative performance evaluation and protocol optimization in high-resolution SPECT imaging.

Investigation of the stability of energy-based scatter estimation in PET (#2546)

SeyedAmir ZamanPour, Ahmadreza Rezaei, Johan Nuyts, Georg Schramm

KU Leuven, Department of Imaging and Pathology, Leuven, Belgium

Abstract

Energy-based scatter estimation in PET estimates scatter from the energy information of detected photon pairs, without relying on an attenuation map. Recent work demonstrated promising results using a model that decomposes the 2D energy histogram into true and scattered coincidences via three basis functions. This model rests on two fundamental assumptions. First, that the **shape** of the scattered energy spectrum is sufficiently stable across varying activity distributions and time-of-flight (TOF) bins to be represented by fixed weights on two basis functions ($c_1 p_1 + c_2 p_2$). Second, that the scattered and true energy distributions remain **statistically distinguishable** given the finite energy resolution of the scanner: when low-angle Compton scatter dominates (as in LORs through high-contrast hot regions at central TOF bins) the scatter spectrum shifts towards 511 keV and the two distributions may become so spectrally similar that reliable decomposition is mathematically infeasible, regardless of counting statistics. In this work, we investigate the validity of both assumptions using long MCGPU-PET Monte Carlo simulations of an elliptical phantom with hot-sphere inserts of radii 1, 3, and 5 cm and contrast ratios of 1:10 and 1:100. Scattered energy spectra are extracted and inspected across TOF bins, hot-region sizes, and contrast ratios; challenging cases are identified for each assumption; and the feasibility of the nine-component 2D energy histogram decomposition from S.A. Zaman Pour et al. is evaluated.

This work was supported in part by PHS Grant EB029306.

Abstract
The accurate quantification of amyloid-beta (Aβ) plaques with Positron Emission Tomography (PET) is critical for the early diagnosis and management of Alzheimer's Disease (AD). However, the diagnostic accuracy of PET imaging is heavily dependent on the image reconstruction algorithm employed. This study provides a quantitative comparison of three distinct PET image reconstruction methods to determine their efficacy for Aβ plaque identification. Using a clinical AD dataset, each of the three algorithms was applied to generate enhanced PET images. The resulting Aβ burden was quantified using the standardized Centiloid scale(CL), and a rigorous statistical analysis was performed to evaluate the performance differences between the methods. Identifying the optimal reconstruction technique is paramount, as its implementation can lead to more sensitive early detection of AD, improved monitoring of disease progression, and ultimately, the enhancement of therapeutic outcomes.

Abstract
Generating accurate attenuation maps from CT images is essential for quantitative PET/CT imaging, while minimising radiation exposure is also important. In conventional CT, the attenuation contributions from Compton effect and photoelectric absorption are combined into a single attenuation value and transformed together from the CT energy spectrum to the PET imaging energy, despite their different energy dependencies. In contrast, spectral CT enables separate electron density and effective atomic number images to be reconstructed. This allows to transform the relevant Compton attenuation contribution independently by applying a scaling factor to the electron density image. In this study, we compare attenuation maps obtained using this approach with those obtained via a bilinear transformation. Measurements of phantoms containing various tissue-equivalent inserts are performed using a PET/CT with twin-beam dual-energy capability and a photon-counting CT. In additional measurements, selected inserts are replaced by compartments containing activity in order to evaluate the effect of

the different attenuation maps on reconstructed PET images. The measurements are performed across a wide dose range to investigate how far the radiation dose can be reduced while still obtaining accurate attenuation maps. Preliminary results show good agreement between attenuation values obtained at different dose levels, with the highest discrepancies between both transformation methods observed for bone-equivalent inserts.
Using electron density and effective atomic number reconstructions from spectral scanners to generate attenuation correction values may improve quantitative PET imaging.

Abstract
Single scatter simulation (SSS) combined with tail-fitting is the standard analytical method for scatter correction in PET. Extending SSS to time-of-flight (TOF) data requires non-trivial adaptations to the scatter kernel. The open-source Software for Tomographic Image Reconstruction (STIR) library has a widely used implementation of SSS for non-TOF data. Here, we present a fully TOF-aware SSS implementation in STIR with two contributions: (i) the TOF kernel ε_t in the scatter-arm emission integral is computed via erf (error function) as opposed to central point approximation in Watson, avoiding the need for an extra normalisation step. (ii) re-use of cached integrals from the non-TOF implementation. The implementation is validated against MCGPU Monte Carlo on a 9-ring compact PET scanner (27 TOF bins, 169 ps, uniform phantom), confirming strong agreement with MC single scatter (r=0.985 full 4-D sinogram; r=0.994 TOF-summed spatial). This contribution opens the door to fully quantitative PET reconstructions for TOF-PET in STIR.

Event-by-Event Energy-Based Scatter Correction via Bayesian Likelihood Estimation (#3026)

Mohammadreza Teimoorisichani

Siemens Medical Solutions USA Inc., Knoxville, USA

Abstract

Energy-based scatter (EBS) correction is increasingly utilized in PET image reconstruction. This work introduces a novel EBS framework that assigns scatter probabilities to individual listmode events via analytical Bayesian calculations. The method utilizes pre-defined energy distributions of scatter kernels as basis functions. By analyzing the global energy spectrum, the algorithm estimates the fractional probability for each event type and subsequently calculates the likelihood of Compton scattering for individual coincidences. The approach was validated using two phantom datasets acquired on a Biograph Vision PET/CT scanner (Siemens Healthineers). Reconstructed images were compared against standard vendor-implemented single-scatter simulation (SSS) with tail-fitting. Results demonstrate high consistency, with scatter fraction estimates differing by less than 3% from SSS. Furthermore, uniform and NEMA image quality phantom analyses showed less than 1% divergence in contrast recovery and background variability. These findings suggest that the proposed EBS method provides a robust, computationally efficient alternative for scatter estimation in clinical PET reconstruction.

Synthetic CT Generation for Attenuation Correction in Respiratory-Gated Rb-82 Cardiac PET Using 3D Diffusion Models (#3061)

Boxiao Yu[1], Wenyuan Qi[2], Jeff Kolthammer[2], Kuang Gong[1]

[1] University of Florida, J. Crayton Pruitt Family Department of Biomedical Engineering, Gainesville, USA; [2] Canon Medical Research USA, Inc., Vernon Hills, USA

Abstract

Accurate attenuation correction (AC) using computed tomography (CT) is critical for quantitative PET imaging. However, in respiratory-gated cardiac PET, respiratory phase mismatch between gated PET and CT can compromise the accuracy of CT-based AC, while acquiring additional phase-matched CT scans is impractical due to radiation dose concerns. To address these limitations, we employed a 3D Denoising Diffusion Probabilistic Model (DDPM) to generate synthetic CT images directly from non-attenuation corrected (NAC) PET data for gated PET AC. The model was trained using paired non-gated Rb-82 myocardial perfusion PET scans and CT-derived attenuation maps, and directly applied to respiratory-gated PET without retraining. Visual evaluation showed that 3D DDPM generated synthetic CT images with superior anatomical fidelity and improved respiratory phase alignment with gated PET compared with 3D GAN, 3D UNet, and 2D DDPM. Regional quantitative analysis near the diaphragm further demonstrated that 3D DDPM achieved improved attenuation correction in regions most affected by respiratory mismatch.

Beyond the Single-Tissue Voxel:A Spin-Echo–Based Multi-Tissue Decomposition Framework with Implications for Synthetic MRI and Machine Learning Diagnosis (#1194)

Abstract

Conventional synthetic MRI generates contrast images from a single effective set of voxel-wise quantitative parameters: proton density (PD), T1, and T2, which may be insufficient when any two or all three of gray matter (GM), white matter (WM), and cerebrospinal fluid (CSF) coexist within the same image voxel. This work presents an exploratory framework using the standard spin-echo signal generation model with a purity-weighted Expectation-Maximization algorithm for tissue prototype estimation that systematically quantifies the prevalence of such multi-tissue voxels. From three co-registered spin-echo MR brain images at distinct Time to Echo (TE), Time to Repetition (TR) settings, per-voxel PD, T1, and T2 relaxation maps are recovered via a robust nonlinear inversion pipeline and validated by re-synthesizing the original images. Each voxel is then decomposed into fractional contributions of GM, WM, and CSF using three methodologically independent models: a Signal-Domain Mixture Model, Parameter-Domain Mixture Model and Mean Parameter-Domain Mixture Model. All three consistently show that 52% – 62% of brain image voxels contain contributions from multiple tissue types, demonstrating model-independently that the single-effective-parameter representation is insufficient in most brain voxels and that conventional synMRI parameter maps can be systematically biased. A tissue-aware synthesis framework is proposed that generates physically grounded MRI contrasts across the full spin-echo (TE, TR) measurement space, providing a quantitative basis for more reliable synthetic MRI. Future work will extend this framework to multi-subject validation and evaluate the synthesized contrast library for machine learning-based lesion diagnosis.

Abstract

In prior work, deep-learning (DL) based denoising was demonstrated to be capable of yielding images comparable to standard-dose studies when the imaging dose is reduced several-fold in pediatric Tc-99m DMSA renal SPECT, based on both quantitative image quality metrics and visual assessment by clinical experts. In this study, we further evaluate the diagnostic utility of DL-denoised images by employing a DL-based classifier to perform a task-based assessment of cortical defects, where a 3D convolutional neural network (CNN) was used to differentiate kidneys with cortical defects from those with normal uptake. We demonstrated this approach with a set of clinical data acquired from 956 subjects, with performance quantified using receiver-operating characteristic (ROC) analysis. The results showed that, without DL denoising, the quarter-dose data achieved a lower classification performance than the full-dose in terms of the area under the ROC curve (p-value < 0.001); however, with DL denoising, the quarter-dose data achieved a statistically comparable performance to that of the full-dose data (p-value = 0.452).

Automated Coronary Artery Extraction up to Distal Vessels Based on Hessian Matrix and 3D Skeletonization to Compensate for Incomplete Labels (#1528)

Ryutaro Ide[1], Koichi Ogawa[2]

[1] Hosei University, Applied Informatics, Graduate School of Science and Engineering, Tokyo, Japan; [2] Hosei University, Applied Informatics, Faculty of Science and Engineering, Tokyo, Japan

Abstract

While deep learning has become the mainstream approach for coronary artery extraction from coronary computed tomography angiography (CCTA) images, its reliance on training data makes it difficult to accurately extract fine distal vessels using existing datasets with insufficient annotations. Therefore, this study proposes a hybrid extraction method utilizing image feature analysis. This method consists of three stages. First, an initial extraction is performed based on anatomical features and CT values. Second, a chained connection algorithm combining tubular structure enhancement via the Hessian matrix and three-dimensional (3D) skeletonization is employed to connect vessel fragments through local search, thereby recovering continuity. Third, volume expansion is performed using an adaptive threshold corresponding to local intensity to restore the accurate vessel diameter. Application of this method to an open dataset demonstrated extreme robustness against CT value degradation caused by insufficient contrast agent perfusion. We successfully extracted and reconstructed fine distal vessels that were missing in the existing labels while maintaining their continuity. Future work involves collaborating with clinical specialists to reconstruct high-quality ground truth labels and conduct rigorous quantitative evaluations.

Abstract

Optical coherence tomography (OCT) provides non-invasive retinal biomarkers that may reflect the distinct neurodegenerative patterns of underlying proteinopathies. This study evaluates a machine learning framework to classify synucleinopathies (Parkinson’s disease [PD] and multiple system atrophy [MSA]) and tauopathies (progressive supranuclear palsy [PSP]) using retinal layer morphometry. Several classification tasks were assessed, ranging from healthy control (HC) discrimination to the differential classification of proteinopathic groups. XGBoost was employed as the primary classifier and evaluated using nested cross-validation. To minimize intra-subject variability, only the most recent visit per patient was included, with features aggregated as the average of both eyes to represent bilateral neurodegenerative involvement. The model demonstrated notable efficacy in distinguishing synucleinopathies (PD+MSA) from tauopathies (PSP), achieving an accuracy of 0.704 ± 0.057. This performance was comparable to the binary classification of HCs vs. all pathological cases (0.724 ± 0.079). In contrast, multi-class settings proved more challenging. These findings suggest that while fine-grained clinical subtype differentiation remains a challenge, OCT-derived biomarkers are highly effective at capturing the broad divergent impacts of alpha-synuclein and tau pathology on the retina.

Multi-step Nonlinear Iteration Method for ECT Energy Spectrum Decomposition (#1885)

Junxu Mu, Zhenrui Lu, Jiangpeng Peng, Zerui Yu, Dongdong Bi, Shaohui An

United Imaging Healthcare Co., Ltd, MI BU Detector R&D Center, Shanghai, China

Abstract

Theranostic radionuclide molecular imaging represents a core technology in precision nuclear medicine. However, its clinical application is hindered by scatter interference and complex background signals in spectral analysis. To address this bottleneck, this paper proposes a multi-step nonlinear iterative method for energy spectrum background subtraction and full-energy peak analysis, suitable for emission computed tomography detectors. The method realizes high-precision background subtraction and peak stripping via a systematic workflow consisting of peak localization, Log-Log-Square root transformation, interval iterative calculation, and Gaussian fitting. Experimental validation is conducted under both single-nuclide and multi-nuclide conditions. The results demonstrate that the proposed method can effectively separate full-energy peaks submerged by scatter in single-nuclide spectra. For the CsI detector, the energy resolution is improved from 12.9% to10.97%. For multi-nuclide and multi-peak spectra, it successfully separates overlapping peaks, suppresses Compton continuum interference, and optimizes energy resolution to around 10.6%. This method improves detector energy resolution, provides solid technical support for the clinical translation of theranostic radionuclide molecular imaging, and exhibits favorable adaptability and correction accuracy. Future work will focus on optimizing iterative efficiency and extending the method's applicability to more complex clinical scenarios.

Abstract

The differential diagnosis of neurological disorders such as Alzheimer's disease (AD), frontotemporal dementia (FTD), Parkinson's disease (PD), and multiple sclerosis (MS) remains a clinical challenge due to overlapping neuroanatomical atrophy patterns in structural Magnetic Resonance Imaging (MRI). This work investigates whether low-dimensional embeddings derived from T1-weighted MRI can reveal a consistent neuroanatomical organisation across these conditions. Using a dataset of 528 subjects, we compared two feature extraction strategies: (i) high-dimensional voxel-wise representations and (ii) regional embeddings based on the Automated Anatomical Labeling (AAL) atlas (116 regions). Dimensionality reduction was performed using Principal Component Analysis (PCA) followed by Uniform Manifold Approximation and Projection (UMAP) to project subjects into a two-dimensional manifold embedding. Our results demonstrate that the neuroanatomical manifold is remarkably scale-invariant as both voxel-wise and regional embeddings yielded consistent topological distributions. Centroid distance analysis in the embedding space revealed a progressive deviation from the HC baseline across disorders. Interestingly, while the model was built on the HC-AD axis, MS and FTD cohorts exhibited the largest structural displacements

(d_{MS}=7.24, d_{FTD}=5.59) compared to AD (dAD=3.57) and PD (d_{PD}=4.27). These findings suggest that low-dimensional manifold representations derived from structural MRI are robust to spatial aggregation and may provide an interpretable framework for studying shared and disease-specific brain alterations across heterogeneous neurological disorders.

Abstract
This paper presents the development of a high-performance Compton camera for targeted radionuclide therapy within the framework of the European project AIDER. The camera is composed of two detector planes, each made of four $LaBr_3$ or $CeBr_3$ monolithic crystals of 50 mm x 50 mm size coupled to Silicon Photomultiplier (SiPM) arrays. In order to determine the optimum pixel size, a hybrid analysis approach based on convolutional neural networks (CNN) and dense networks (DNN) has been developed to estimate the interaction position of the photons. Starting from Monte Carlo simulation data (GATE v7.0) and using a reference based on an analytical model, the proposed alternative incorporates the systematic error of this model as an additional input for the NNs. This achieves active correction of the edge effect and improves the overall spatial resolution (FWHM) from a range of 1.80–2.25 mm down to 0.63–0.70 mm. Results show the benefits of the combined NN approach and indicate the possibility of employing SiPM arrays with large pixel sizes, effectively restricting the amount of readout channels. Experimental tests are ongoing.

Abstract

This study evaluates the suitability of spatial registration in deep learning for neuroimaging, focusing on the balance between reducing inter-subject anatomical variability and preserving data fidelity. We hypothesize that processing images in their native anatomical space avoids morphological distortions introduced by registration, enabling neural networks to detect subtle structural biomarkers that may be altered in normalized spaces. To test this, a standard densely connected neural network was used to classify two balanced cohorts: one focused on the diagnosis of Parkinson's disease (PD) and the other on the diagnosis of Alzheimer's disease (AD). The experimental design compared four input modalities: whole-brain volumes and gray matter maps, each in native space and registered to a standard reference space. For PD classification, native and registered spaces achieved similar accuracy, although registration produced a marked imbalance between sensitivity and specificity. For AD, the best performance was obtained using gray matter in native space, confirming that preserving topological integrity is critical in pathologies with pronounced atrophy. These findings suggest that spatial registration should not be considered an indispensable preprocessing step in deep learning-based neuroimaging, but rather a methodological choice that must be evaluated based on the task and dataset. Processing in native space is an effective alternative

that simplifies preprocessing while preserving diagnostically relevant information, opening future research directions on model robustness to anatomical variability without prior transformation.

Edge-Guided Deformation Field Fusion for Robust PET Motion Correction (#2650)

Qiong Liu, Wenyuan Qi, Jeff Kolthammer

Canon Medical Research USA, Vernon Hills, USA

The authors have no disclosures to report.

Abstract
Non-rigid motion correction for gated PET is challenging due to low contrast and high noise in homogeneous regions, where deformation estimates may drift, while strong smoothness regularization can oversmooth boundaries and suppress localized motion near lesions. We propose an edge-guided flow fusion method that combines two deformation fields predicted by identical registration architectures trained with different smoothness weights. For each moving--fixed PET pair, we compute an edge probability map from the gradient magnitude of the Gaussian-smoothed absolute intensity difference, followed by percentile normalization and logistic mapping. After thresholding and morphological dilation, the resulting mask defines an edge-dominant region. We fuse the two predicted flows by selecting the low-regularization flow near edges and the high-regularization flow in homogeneous background regions, then warp the moving PET volume using a spatial transformer. This approach preserves deformation flexibility at boundaries while maintaining smooth motion in low-contrast regions, without changing network architecture.

Abstract

PET detectors often use a Center of Gravity (CoG) algorithm applied to the output signal of sensor modules to perform coordinate reconstruction. CoG assumes that the spread of optical photons emitted by a pixelated scintillator crystal is symmetric about the point of interaction. A photoelectric (PE) event, where energy is deposited within a single scintillator pixel, produces such a distribution. Inter-crystal scatter (ICS) events, however, occur when a gamma photon deposits energy into multiple scintillator pixels, producing multiple photon distributions that degrade CoG accuracy and spatial resolution. Convolutional neural networks (CNNs) have proven effective for identifying and recovering ICS events in simulated data and in real systems when trained on experimentally acquired datasets, typically obtained using collimated measurements to isolate scintillator pixels. However, acquiring collimated datasets is time-consuming and requires high precision, motivating the use of simulated data as a primary training source. In this work, PET data was generated using GATE and used to train a small CNN to identify and remove ICS events based on softmax confidence values for a detector consisting of a 24×24 LYSO array coupled to an 8×8 SiPM array. A NU-4 image quality phantom and Na-22 point source acquired on a clinical system demonstrated improvements in recovery coefficient (RC) and peak-to-valley ratio for all RC five rod sizes, along with modest improvements in spatial resolution and spill-over ratio. The results demonstrate the feasibility of using imulated data as a primary training source for ICS filtering and recovery. Thus, a hybrid approach incorporating limited real data may further improve performance without requiring a large number of collimated acquisitions.

Temporally and Spatially-Variant Penalty for Dynamic PET Reconstruction (#2858)

Nasrin Taheri[1], Thomas Carlier[2], Simon Stute[2]

[1] CRCI2NA, INSERM UMR 1307, Nantes University, Nantes, France; [2] Nuclear Medicine Department, Nantes University Hospital, Nantes, France

Abstract

Dynamic PET reconstruction is challenging due to strong temporal variations in count statistics, leading to non-uniform noise and spatial resolution across frames. In this work, we simply extend previous works to propose a temporally and spatially-variant regularization strategy for dynamic penalized maximum-likelihood (PML) reconstruction based on a time-and-space-dependent modulation factor derived from the Fisher information matrix. A modified estimation of the modulation factor is used to improve robustness in low-count conditions by removing dependence on noisy measurements. The method was evaluated using dynamic FDG simulations based on the 2D Zubal brain phantom and compared with OSEM and PML reconstruction without modulation.

Results showed improved preservation of anatomical structures and lower RMSE values in the cortex, putamen, and caudate regions while avoiding the excessive smoothing observed with conventional PML reconstruction. These results suggest that automatic temporally and spatially adaptive regularization can improve image quality and quantitative accuracy in dynamic PET imaging.

Abstract

This study applies the Statistical Agnostic Regression (SAR) methodology to validate predictive model for brain aging using gray matter functional connectivity derived from fMRI data from the UK Biobank database. The method evaluates significant linear relationships between age and functional connectivity correlation matrices, by resampling and estimating an upper bound on the expected risk through a Bayesian threshold under the worst-case scenario. The SAR power quantifies the probability of detecting a true linear relationship using the expected risk statistic, via Monte Carlo simulations under the null distribution. Predictive performance is assessed through Principal Component Analysis (PCA) applied to the global correlation matrices, which are constructed from subjects whose ages fall within the extreme percentiles (below the 15th and above the 85th percentile). This framework enables the identification of connectivity signatures associated with aging within a unified representation of functional brain connectivity dynamics. Functional connectivity matrices of gray matter were computed from preprocessed fMRI data by extracting region-wise time series and estimating pairwise statistical dependencies using Pearson correlation coefficients. The results support the development of a statistically significant model for predicting age from functional connectivity correlation matrices and demonstrate that combining rigorously validated predictive models with SAR and PCA methodologies can characterize age-related variability in functional connectivity and improve understanding of brain aging using large-scale population neuroimaging data.

Interpreting Prognostic [^{18}F]FDG PET Radiomic Signatures Using Parametric Tumour Simulation (#1849)

Lara M. Bonney[1,2], Kevin M. Bradley[3], Andrew B. Hassan[1], Daniel R. McGowan[2,4]

[1] University of Oxford, Sir William Dunn School of Pathology, Oxford, UK; [2] Oxford University Hospitals NHS Foundation Trust, Department of Medical Physics and Clinical Engineering, Oxford, UK; [3] Cardiff University, Wales Research and Diagnostic Positron Emission Tomography Imaging Centre (PETIC), Cardiff, UK; [4] University of Oxford, Department of Oncology, Oxford, UK

Abstract

Radiomic features derived from [^{18}F]FDG PET/CT imaging can quantify intratumoural spatial heterogeneity and have demonstrated prognostic utility across multiple oncological indications, including sarcoma. However, the biological interpretation of radiomic risk scores remains poorly understood, partly due to confounding in clinical datasets and the absence of ground-truth tumour parameters. A simulation-based approach offers a controlled framework for mapping image-derived features to biologically and physically meaningful tumour properties.

In this study, a parametric tumour model incorporating eight biologically motivated parameters—including uptake intensity, radial signal gradients, compartmental structure, multifocal uptake, and morphological deformation—was used to generate 1,024 synthetic tumour volumes across physiologically plausible parameter ranges. In parallel, a prognostic radiomic risk score was derived from [^{18}F]FDG PET/CT images of 115 sarcoma patients enrolled in the Oxford Precision Oncology for Sarcoma (OxPOS) study. This trained model was subsequently applied to each simulated volume to infer a radiomic risk score, and correlation analysis identified simulation parameters most strongly associated with predicted risk.

Three parameters; baseline uptake intensity, radial signal gradient, and fractional high-uptake volume, exhibited moderate but statistically significant correlations with the model-derived risk score ($|r|$= 0.41, 0.38, and 0.52, respectively). These findings provide mechanistic insight consistent with known tumour biology; for example, elevated radial signal gradients are characteristic of tumours with necrotic cores.

This work demonstrates the utility of simulation for enhancing biological interpretability and communicability of radiomic prognostic models. Ongoing work aims to expand the simulation framework and integrate genomic data to further elucidate the biological underpinnings of radiomic signatures in sarcoma.

Parameter Estimation of Arterial Input Function Using Nonlinear Mixed-Effects Modeling With Reduced Sampling (#2685)

Junan Jiang[2], Zirui Jiang[1], Junyu Chen[1], Yong Du[1]

[1] Johns Hopkins University School of Medicine, Department of Radiology, Baltimore, USA; [2] Johns Hopkins University Whiting School of Engineering, Department of Applied Mathematics and Statistics, Baltimore, USA

Abstract

Dynamic positron emission tomography (PET) requires dense arterial blood sampling to estimate arterial input functions (AIFs), creating substantial clinical burden and limiting practical implementation. To reduce number of samples, we developed a data-driven method for AIF estimation under sparse sampling conditions using nonlinear mixed-effects modeling. The study dataset included 90-min dynamic brain PET AIF data from 26 healthy subjects acquired with the 11C-DPA-713. A three-exponential nonlinear mixed-effects model was used to characterize the AIF, with fixed effects representing population-level kinetics and random effects capturing inter-individual variability. The AIF was modeled using a deterministic five-point subsampling strategy that selected representative early, intermediate, and late decay-phase observations. Model parameters were estimated using the stochastic approximation expectation maximization algorithm, and reduced-sampling predictions were compared with reference ground truth generated from the full dataset. The reduced five-point strategy produced AIF estimates that closely matched the full-data reference, yielding a root mean squared error of 0.37 and a mean relative error of ranging from 19% to 27.8%. Visual comparisons further demonstrated strong agreement between predicted and reference AIFs across subjects, indicating that plasma activity characteristics were preserved despite reduction in sampling density. These findings suggest that sparse sampling combined with nonlinear mixed-effects modeling can provide reliable AIF estimation while reducing the burden of arterial blood collection in dynamic PET studies.

Abstract

Thyroid eye disease (TED), the most common autoimmune orbital disorder and a major cause of orbital morbidity, is still assessed largely through subjective clinical measures. Although orbital MRI radiomics offers potential quantitative biomarkers for disease activity and treatment response, the reproducibility of these features under real-world imaging variability has not been systematically evaluated, limiting clinical translation. We performed a perturbation-based stability analysis using 150 patients from the public TOM500 dataset, extracting 293 radiomic features from seven Image Biomarker Standardization Initiative (IBSI)-compliant families across nine bilateral orbital structures using original and Laplacian-of-Gaussian filtered MRI images. We used ten perturbations per patient with combined rigid transformations, Gaussian noise, and 1-voxel mask modifications, and assessed stability using ICC(A,1). Across 2,637 structure-feature combinations, mean ICC was 0.72, and 53% of features achieved Good or Excellent stability (ICC ≥ 0.75). The medial rectus (ICC 0.84), followed by superior rectus and optic nerve (both 0.81) were the most robust structures, whereas the eyeball (0.55) and lateral rectus (0.61) were least stable. Laplacian-of-Gaussian filtering improved texture feature reproducibility, increasing median texture ICC from 0.73 to 0.80 and enhancing stability in medial rectus, lacrimal gland, and orbital fat features. Stability rankings were nearly identical between active and inactive disease groups (Pearson r = 0.92), indicating that disease severity did not influence feature reliability. These findings provide the first large-scale reproducibility assessment of orbital MRI radiomics in TED and establish a foundation for future biomarker and predictive modeling studies.

This work was supported by the MERCUR graduate school “Präzisionsprotonentherapie — Praxisbezogene Physik und Chemie an der Schnittstelle zur Medizin” (grant-number St-2019-0007).

Abstract

The aim of the study was to investigate whether proton therapy fields can be verified in vivo during treatment using film-based transit portal dosimetry. Potential clinical treatment plans were checked for downstream dose contributions. The complete proton portal imaging workflow was verified in experiments with an anthropomorphic phantom. Head-and-neck, mediastinal, thoracic, abdominal and cranio-spinal axis irradiations (CSIs) yielded downstream dose areas, which enable portal imaging. The cranial fields of CSI plans were deemed as most suitable and tested with the phantom in a simplified setup. Radiochromic films, mounted on top of the patient couch, served as portal imaging detectors. Phantom tests indicate that the patient setup can be verified within an accuracy of ≈1 mm per direction. In conclusion, a novel, straight-forward procedure has been developed for in-vivo dosimetry in proton therapy for some patients with specific indications.

This research was supported by the National Cancer Center Korea (NCC-2410960).

Abstract

We developed a patient-specific volumetric dosimetry system using a tumor-shaped plastic scintillator derived from patient MR images for integral dose verification in Gamma Knife radiosurgery. Three tumor model scintillators (TMSs) representing a vestibular schwannoma (0.39 cm³) were irradiated using a nine-shot plan prescribing 8 Gy to the 60% isodose line. The integral dose, defined as the energy absorbed over the entire tumor volume, was measured and compared with the value calculated by the Leksell GammaPlan® treatment planning system. Two independent calibration methods were employed: calibration at a secondary standard dosimetry laboratory and Monte Carlo simulation-based calibration using Geant4. The integral dose measured by the simulation-based calibration was (2.00[if gte msEquation 12]><m:oMath><span lang=EN-US style='font-size:10.0pt;font-family:"Cambria Math",serif; mso-fareast-font-family:"맑은 고딕";mso-fareast-theme-font:minor-fareast; mso-bidi-font-family:"Times New Roman";mso-ansi-language:EN-US;mso-fareast-language: EN-US;mso-bidi-language:AR-SA'><m:r><m:rPr><m:scr m:val="roman"/><m:sty m:val="bi"/></m:rPr>±</m:r></m:oMath><![endif] 0.76)% higher than the planned value of 5.01 mJ, falling within the acceptable 3% tolerance for Gamma Knife absolute dosimetry. The laboratory-based calibration yielded an integral dose (5.84[if gte msEquation 12]><m:oMath><span lang=EN-US style='font-size:10.0pt;font-family:"Cambria Math",serif; mso-fareast-font-family:"맑은 고딕";mso-fareast-theme-font:minor-fareast; mso-bidi-font-family:"Times New Roman";mso-ansi-language:EN-US;mso-fareast-language: EN-US;mso-bidi-language:AR-SA'><m:r><m:rPr><m:scr m:val="roman"/><m:sty m:val="bi"/></m:rPr>±</m:r></m:oMath><![endif] 3.56)% lower than the reference value of 4.30 mJ; the larger deviation is attributed to probe reassembly uncertainty and the angular dependence of the calibration coefficient. These results demonstrate that the TMS system can serve as a practical tool for verifying the three-dimensional integral dose calculated by a treatment planning system.

MIC-10-326

Attenuation Correction for Targeted Alpha Therapy Monitoring with Compton Camera MACACO III+ (#1402)

Yuemeng Feng[1], Jorge Roser[1], Julius Werner[1], Jona Kasprzak[1], Luis Barrientos[2], Siddharth Parashari[2], Karol Brzeziński[2], Gabriela Llosá[2], Magdalena Rafecas[1]

[1] University of Luebeck, Institute of Medical Engineering, Luebeck, Germany; [2] University of Valencia, Institute for Corpuscular Physics, Valencia, Spain

The authors acknowledge the Advanced Imaging DEtector for targeted Radionuclide therapy (AIDER) programme (Grant agreement ID: 101165088), funded under the Euratom Research and Training Programme (EURATOM).

Abstract

Compton cameras are being explored as a promising technique for treatment monitoring of targeted alpha therapy, by imaging the gamma emissions produced during the decay of the alpha-emitting radionuclides. To improve image accuracy, attenuation correction is essential. Here we analyze the effects achieved by incorporating attenuation correction into the list-mode MLEM reconstruction of MACACO III+ synthetic data using ideal simulation. The results demonstrate that, without attenuation correction, contrast recovery coefficients of 97.2%, 84.7%, 73.5%, 47.8% are achieved for rods with diameters of 6, 5, 4 and 3 mm, respectively, using a total activity of 0.135 MBq of 440 keV gammas, a major gamma peak in the decay of ^{225}Ac and a hot to background ratio 10:1, simulated over 2 hours. Combined energy reconstruction at 218 and 440 keV yields improved image contrast when attenuation correction is applied. This work was carried out within the frame of the Advanced Imaging DEtector for targeted Radionuclide therapy (AIDER) project.

Abstract

Positron emission tomography (PET) is an effective non-invasive modality for in vivo range verification in carbon-ion therapy. This study evaluates an all-digital PET system for in-beam monitoring of carbon-ion treatment plans. Clinical DICOM RT plans were converted into a GATE/Geant4 model of single-field pencil beam scanning (PBS) carbon-ion irradiation in a polymethylmethacrylate (PMMA) phantom. Simulated dose and positron-emitter distributions were compared with treatment planning system (TPS) dose and measured PET data. TPS and GATE showed good dosimetric agreement, with nearly identical planning target volume (PTV) D50% and a 3D gamma passing rate of 97.66% (2%/2 mm). PET validation yielded R50,sim = 124.33 mm and R50,exp = 125.00 mm, corresponding to ΔR50 = 0.67 mm. These results support millimeter-level PET-based range verification for carbon-ion therapy.

Performance of a state-of-the-art ToF-PET detector in a proton therapy in-beam radiation environment (#1485)

Thomas Fogg, Peter Dendooven

University Medical Center Groningen, Particle Therapy Research Center & Department of Radiation Oncology, Groningen, Netherlands

Abstract

In-vivo positron emission tomography (PET) imaging of positron emitters produced by the therapeutic proton beam in the patient is a well-studied irradiation verification tool. Adaptive treatment planning benefits from fast feedback, down to the sub-second time scale, requiring an in-beam PET scanner operating during beam delivery for N-12 imaging. Use in clinical routine requires that the performance of such detectors is not significantly affected by radiation exposure over time. We have studied the performance of four state-of-the-art time-of-flight Hamamatsu C13500-4075YC-12 (ToF)-PET detectors in a proton therapy radiation environment. A 150 MeV proton beam (pulsed with intensities of 0.3, 1 and 3 nA at 10% and 1.5% duty cycles) was stopped in PMMA phantoms whilst PET data was acquired. The coincidence energy spectra obtained in-beam (both with the beam on and between beam pulses) show the N-12 511 keV peak. As the experiment progressed, the data output shows cumulative faults from an increasing percentage of corrupt events. Whilst the accumulation of these faults was partially mitigated by system resets during the experiment, comparison of data acquisitions with a combined Na-22 & Ga-68 source before and after the experiment show that the performance degradation is long-lasting, although the detectors show signs of recovery 5 months later.

Abstract

Proton and heavy-ion therapy exploits the Bragg peak to concentrate dose within the tumor while sparing surrounding normal tissues; however, range uncertainties necessitate conservative safety margins and restrict clinical indications. To address this, we are developing an in-beam All-Digital positron emission tomography (PET) platform for dose-guided particle therapy. Two prototype systems have been designed, built, and tested at multiple proton and heavy-ion therapy centers: a 12-module pre-clinical partial-ring system for phantom and small-animal studies, and a 16-module research-clinical open-ring system for human-subject trials. Both employ lutetium-yttrium oxyorthosilicate scintillators read out via the multi-voltage threshold digitization architecture. In-beam PET imaging of proton-induced positron activity has been demonstrated in polymethyl methacrylate phantoms with approximately 1 mm range agreement, and in live rats where biological washout effects on image contrast were observed. A three-phase development roadmap is presented, progressing from online range monitoring to adaptive therapy and ultimately real-time feedforward therapy, aiming to narrow safety margins, broaden treatment indications, and provide the verification infrastructure for FLASH therapy.

MIC-10-338

Feasibility Study of In-Beam Range Verification Using Pixelated CZT Detectors in Carbon Ion Therapy (#1646)

Dian Guo, Jianxiong Shao, Xiangdong Cai, Chunhui Zhang, Yongzhi Yin

Lanzhou University, LanZhou, China

Abstract

To overcome the limitations of existing beam range verification methods in terms of detection efficiency, system complexity, and real-time capability, this study proposes a carbon ion beam range verification method based on a pixelated cadmium zinc telluride (CZT) detector and machine learning. The pixelated CZT detector was used to measure the secondary particle response generated during carbon ion irradiation of a polymethyl methacrylate

(PMMA) target, and a machine learning regression model was then applied to predict the beam range. The experimental results demonstrate that the pixelated CZT detector can accurately measure secondary particle responses. In addition, the effects of different detection regions, defined by pixel ranges, were investigated at a monitor unit (MU) setting of 6 × 10⁶. Using data from a 16 × 16 pixel region, the proposed method achieved a mean absolute error (MAE) of 0.79 mm. These results indicate that the proposed approach provides a feasible technical strategy for online range verification in carbon ion beam therapy

Abstract
Laser-driven sources of ionizing radiation provide unique possibilities for studying ground-breaking phenomena and for exploring novel applications of compact accelerators. An outstanding example is the controlled irradiation of biological samples with laser-accelerated, high-energy particles. After a pilot experiment at the Spanish Pulsed Laser Center (CLPU), the aim of the present study is an increase of the single-shot dose and the mean dose rate on monolayer cell cultures. Two possible scenarios at the same laboratory have been considered. On the one hand, the previous setup at the VEGA-3 laser line may be upgraded through a set of permanent quadrupole magnets to focalize the proton beam closely behind the laser target. On the other hand, a similar, more compact arrangement inside the VEGA-2 target vessel benefits from shorter flight paths and a 10-fold higher repetition rate. Particle tracking simulations with realistic beam control elements point towards a 5–15 times increase in proton fluence and single-shot dose.

Abstract

Proton therapy is an advanced radiotherapy modality whose clinical advantage arises from the highly localized dose deposition produced at the Bragg peak. However, this feature makes the technique highly sensitive to uncertainties in patient positioning, anatomical changes, and beam delivery. Verifying the dose delivered to patients after treatment session is therefore essential to ensure treatment safety and reducing planning margins. During proton irradiation, nuclear interactions generate positron-emitting isotopes that can be detected with Positron Emission Tomography (PET). In this work, we focus on the detection of ^{18}F, whose long half-life enables offline PET acquisitions 60–150 min after treatment, when short-lived isotopes have decayed. Because the expected in-vivo ^{18}F activity is very low (0.1–1 Bq/mL), we propose a PET system optimized for low-count imaging, based on BGO scintillation crystals to avoid the intrinsic background of lutetium-based detectors typically used in commercial scanners.

The proposed PET prototype (*INSPIRE*) consists of 16 detector modules arranged in a single ring, each comprising a two-layer pixelated BGO block (19×19 and 20×20 arrays) coupled to a 12×12 SiPM array, thus enabling Depth of Interaction (DOI) information. The system, which has an inner diameter of 26 cm and an axial length of 5 cm, is intended for brain studies. In this work we present the design of the *INSPIRE* system and the experimental characterization of the detector modules, including pixel resolvability, layer separation, and energy performance, together with preliminary proton-irradiation simulations that illustrate the suitability of the ^{18}F signal for offline PET imaging.

Abstract

Real-time monitoring in hadron therapy is essential to account for anatomical shifts and setup uncertainties that may compromise dose delivery. This work evaluates a software framework designed for online range verification via monitoring of the Prompt Gamma (PG) profile, which is know to be correlated to the Bragg peak position. The architecture employs a decoupled simulation pipeline: PG emission is modeled using MC codes, while the detector response is characterized through a dedicated Python-based tool, PGIPY. This simulated new profile, computed spot by spot, is then compared with measurement inside the software. To ensure spot-by-spot clinical correspondence, the software utilizes machine log files to synchronize simulated data with actual delivery sequences.

Experimental validation with an homogenoeus phantom was performed at the CNAO facility (Pavia, Italy). A high degree of correlation was observed between simulated and experimental profiles, confirming that the framework is free from significant systematic modeling errors. These results demonstrate that the proposed pipeline provides a robust, validated baseline for clinical integration, ensuring that any detected profile deviations during treatment are attributable to physical range shifts.

Abstract

Purpose: To enable personalization dosage of ^{177}Lu-based Theranostic radiopharmaceutical therapy (RPT), we are developing a Portable Organ Dosimetry Device (PODD) for at-home use to monitor activity in regions of interest (ROI) such as tumors and organ at risk (OAR). To accurately estimate OAR activity, knowledge of the relative positions of probes and ROIs is required. This can be achieved either by consistency of initially measured locations, or by verifying locations for each measurement. Methods: We have constructed a prototype PODD, and we examine the variation of ROI-location estimates of an NEMA IQ phantom in the PODD reference frame by measuring PODD and ROI features from repeat x-ray CT scan with the phantom removed and replaced in the PODD between measurements. Results: The standard deviations of ROI translational location with the phantom in a supine orientation was 1.0mm axially, 0.2mm horizontally, and 0.1mm vertically. Standard deviations of rotational position were 0.7 degree in tilt and less than 0.1 degrees in roll about the PODD and CT scanner axis. Conclusion: Locating uncertainty of a rigid body phantom within our prototype PODD will not significantly affect the accuracy of time-integrated activity estimates using longitudinal measurements with the phantom removed and replaced in the PODD between measurements. We must repeat these measurements for a realistic deformable phantom or with real subjects.

Abstract
Compton cameras are showing promise for targeted radionuclide therapy (TRT). The IRIS group of IFIC (Valencia, Spain) has developed a scintillator-based Compton camera prototype for medical imaging applications which is being assessed in TRT. The prototype MACACO III+ consists of two detector planes, with the second having an active area four times larger than the first. Previous tests performed on phantoms and small animals using ^{131}I demonstrated the suitability of the system for radiotracer imaging. The system is being employed to obtain initial experimental data with different radionuclides to validate the simulations carried out within the European project AIDER, which will develop a high performance Compton camera. In this work, experimental measurements with MACACO III+ were carried out at La Fe Hospital (Valencia, Spain) to image a vial filled with ^{224}Ra. GATE simulations were also performed to compare with experimental data. In addition, the prototype MACACO IV, composed of two planes with four detectors each, is under development. Simulation studies also include the configuration of the new prototype to assess influence of detector geometry on the overall system performance.

AIDER Compton Camera for Targeted Radionuclide Therapy (#2559)

Gabriela Llosá, On behalf of AIDER Collaboration

Instituto de Física Corpuscular (IFIC), CSIC-UV., Valencia, Spain

This work has received funding from the European Union's EURATOM research and innovation program (AIDER project, G.A. 101061037).

Abstract
Targeted radionulclide therapy (TRT) is a cancer treatment modality that employs radiopharmaceuticals to selectively deliver radiation to cancerous cells at specific target organs. Its use has increased drastically in the last years, and it has been extended to novel radiopharmaceuticals. The secondary photons emitted by the therapeutic radionuclides can be employed for imaging the compound distribution in the patient's body for treatment assessment and dosimetry. A precise quantification of the radiation dose delivered to lesions and organs at risk is crucial for improving patient treatment safety and reducing related side effects. Conventional imaging modalities

are not optimized for such secondary emission, in particular in the case of alpha-emitting radionuclides, which are gaining prominence due to their exceptional cytotoxicity. For targeted alpha therapy (TAT), image-based dosimetry is an unmet need as currently used gamma cameras are not effective in the case of these high energy and low activity emitters. The European project AIDER aims at developing a high-performance scintillator-based Compton camera to improve imaging in TRT and to enable image-based dosimetry in TAT. The project, coordinated by the IRIS group of IFIC, includes four academic partners, two hospitals, an SME and a patient association. Within the project, the system will be developed and tested with phantoms and patients. Initial work on system design optimization and image reconstruction, as well as detector and electronics development has been carried out.

Gamma Detection for Source Localisation in Targeted Alpha Therapy

(#2678)

Chiara De Sio, Lujin AbuSabah, Jinyan Duan, Yuyao Shi, Sean Williams, Jaap Velthuis

University of Bristol, School of Physics, Bristol, UK

Abstract

Targeted alpha therapy delivers highly localised dose, so treatment planning and delivery verification depend on whether the radionuclide source remains at the intended deposition site or is redistributed by diffusion or biological transport. This simulation study tests whether decay-chain gamma emissions can provide a detectable source-localisation signal in an AlphaGlue-like geometry. Photon transport was modelled for a thin loaded glue layer on a water phantom surrounded by six detector panels, with each photon entry into a panel counted as one hit. Seven source configurations were analysed: a retained-source baseline, broad redistribution of 10%, 50%, or 90% of the source in water, and localised displacement of 20%, 40%, or 60% of the source to a compact water region. Each configuration used ten repetitions of 10,000 primary decays and was normalised to a 3 µCi reference source. Total detector-hit yield changed only modestly, but baseline-subtracted spatial hit profiles showed strong source-dependent structure. The central glue-facing signal fell to 0.94, 0.72, and 0.47 of baseline for the broad-redistribution cases, and to 0.84, 0.67, and 0.50 for the localised-displacement cases. Profile-shape features recovered the broad diffusion fraction with an R2 value of 0.998, while a secondary-source metric identified all localised displaced-source cases. The reconstructed displaced-source position was centred at approximately 525–531 mm, compared with the simulated 500 mm source region. Time-window analysis showed that large redistributions reached three-standard-deviation thresholds within 30 minutes to 2 hours; the weakest broad redistribution required about 6 hours, and the 20% localised displacement produced detectable displaced-region

excess within about 1 hour. These results indicate that gamma-hit patterns provide source-location information beyond total count rate and could support activity verification and treatment-delivery monitoring.

Abstract

We present a low-cost lensless radiomicroscopy system for cellular-scale imaging of theranostic radiopharmaceutical uptake using a commercial CMOS image sensor. The device enables simultaneous brightfield and β-emission imaging with sub-10 μm spatial resolution, allowing direct correlation between morphology and radionuclide distribution. The system was validated using β^--emitting 111Ag and β^+-emitting 18F-FDG sources, demonstrating quantitative linearity and accurate radioactive decay measurements. Live-cell experiments on MDA-MB-231 breast cancer cells showed detectable intracellular uptake of 111Ag, while imaging of U87 glioblastoma spheroids revealed spatially localized 18F-FDG accumulation in a warm background environment. These results demonstrate the potential of lensless radiomicroscopy as a compact and affordable platform for quantitative in vitro evaluation of theranostic agents at single-cell and multicellular levels.

Intercrystal Compton Scattering Detection in Pixelated LYSO Detectors via Quantum Localization (#2993)

Amirreza Hashemi, Xi Zhang, Hamid Sabet

Harvard Medical School/Massachusetts General Hospital, Radiology Department, Boston, USA

This work was supported in part by NIH grant R01EB034785.

Abstract

We introduce a novel quantum-inspired method for identifying intercrystal Compton scattering in pixelated scintillation detectors. The approach treats each SiPM readout as a spatial signal and converts it into a discrete eigenfunction representation using a Hamiltonian built from the measured intensity distribution. Event structure is then assessed through quantum localization, quantified by the participation ratio. Single-site events produce highly localized dominant modes, whereas Compton-scattered events produce multiple localized modes associated with distinct interaction sites. A dual criterion based on quantum localization and eigenvalue proximity is used to classify multi-site events without calibration-intensive response modeling or supervised training. The method was evaluated with Geant4 optical photon simulations and measurements from LYSO:Ce detector arrays with thicknesses from 2 to 25 mm. Experimental classification agreed closely with simulation, with differences below 1% for most thicknesses and below 5% in all cases. These results indicate that the proposed representation captures the topology of gamma-ray interactions directly from detector signals.

Abstract

Total-body PET imaging provides unprecedented sensitivity and extended axial coverage but remains affected by partial volume effects (PVE), particularly in small lesions and regions with spatially varying resolution. Conventional deconvolution approaches, such as Richardson–Lucy (RL), can improve spatial resolution but often suffer from noise amplification and inaccuracies in point spread function (PSF) modeling. In this work, we propose a learned unfolded deconvolution framework for robust PVE correction in total-body PET imaging. The method reformulates RL deconvolution as a fixed-depth network in which each iteration explicitly incorporates the system PSF while learnable parameters enable adaptive regularization and noise suppression. Standard-dose [^{18}F]FDG PET images were used as network inputs to isolate the PVE correction problem from low-count noise effects. The model was trained in a self-supervised manner using RL-generated surrogate references, eliminating the need for voxel-wise ground-truth images. Evaluation was performed on multicenter total-body PET datasets acquired from uEXPLORER and Biograph Vision Quadra systems. Quantitative assessment on an independent test set demonstrated high structural fidelity (PSNR = 47.38 ± 5.71, SSIM = 0.98 ± 0.01) and low reconstruction error (RMSE = 0.005 ± 0.003), while maintaining acceptable SUV bias (12.2% ± 23.1%). Qualitative analysis showed improved lesion delineation and enhanced uptake contrast without visible noise amplification. Bootstrap-based analysis further demonstrated stable performance with narrow confidence intervals across metrics. The proposed framework provides an interpretable and robust solution for PVE correction, improving image quality and quantitative consistency in total-body PET imaging.

Abstract

Many studies have proposed methods to estimate internal dosimetry, enabling patient-specific adjustment of radiopharmaceutical therapy. We are developing a practical, low-cost multi-pinhole collimated system (PODD) with on the order of 10 sensors at fixed locations around a subject. Estimation of internal dosimetry to organs at risk is extremely ill-posed with this sparse sensor placement. In this work, we hypothesize that use of objective functions with an accurate forward model and multiple regularization terms can directly estimate total accumulated activity using simulated PODD acquisitions of realistic distributions of Lu-177 DOTATATE. Methods: We developed a custom GPU-based forward projector enabling rapid multi-pinhole detection simulation. We propose an objective function for direct estimation of wash-in, wash-out, and total integrated activity (TIA) kinetic parameters from multi-time point, sparse sensor measurements. This objective function includes regularization based on a) matching sensor measurements to initial time-point SPECT acquisitions and b) promoting kinetic parameters similar to population kinetics. Evaluation was performed by simulating sensor acquisitions from public 4-time point SPECT/CT images (Dewaraja et al, 2021, Lu-177 DOTATATE Anonymized Patient Datasets). Conclusion: Direct estimation of clinically relevant TIA can be performed with on the order of 10 to 20 pinhole-collimated sensors acquiring data at four times post treatment.

Abstract

Highly sensitive long-axial-field-of-view (LAFOV) positron emission tomography (PET) scanners require fast and reliable reconstruction methods, where accurate quantification in short temporal frames is key to kinetic modeling applications. We extended FastPET - a direct neural network reconstruction method based on image loss - with an additional forwardprojection step and data loss penalty, modified the training database to specifically account for short temporal frames and evaluated its PET quantification accuracy in high- and lowcount regimes on the Biograph Vision Quadra. Compared to ordered subset expectation maximation (OSEM, 4i5s, all pass) reconstructions, FastPET based only on image loss resulted in smoothed images and an overshoot in the contrast recovery coefficient (CRC) by up to 20%. A combination of data loss and image loss counteracted this effect but still showed a degraded CRC for frame lengths ≤5s. Including low-count training data in the training stablized the image quality and slightly improved the CRC of small structures in short frames ≤5s.

Abstract

The extension of the axial field-of-view (AFOV) advances in positron emission tomography (PET), offering unprecedented sensitivity and enabling ultra-low-dose 4D total-body imaging. However, long-axial field-of-view (LAFOV) systems introduce significant challenges, including prohibitive computational loads and complex quantitative corrections necessitated by expanded axial acceptance angles. A primary obstacle is the extreme sparsity of acquired data relative to the vast lines-of-response (LOR) space. We present a robust quantitative correction strategy integrated into QuanTOF, a GPU-accelerated, list-mode reconstruction framework. Our primary contribution is the implementation of a modified component-based normalization (CBN) strategy tailored for axial-dependent variations, effectively mitigating noise amplification in sparse data environments. Furthermore, we introduce a simplified calibration protocol utilizing 0.5 m thin-ring and FOV-length line sources to derive geometric and plane efficiencies—an efficient alternative to conventional through-axial rotating rods. To ensure correction accuracy despite data sparsity, a moderate rebinning strategy was employed for scatter and random estimation. The framework was validated via GATE simulations of the 1.5 m uMI Panorama GS system. Reconstruction of a 1.5 m uniform cylinder phantom (8cm radius) demonstrated superior axial uniformity, with intensity fluctuations constrained to less than 2% within 70% of the FOV. Additionally, Derenzo phantom simulations confirmed the framework's high-resolution capabilities, successfully resolving 2.4 mm hot rods. These results show this framework successfully overcomes the inherent challenges of LAFOV data sparsity, securing the quantitative fidelity essential for total-body molecular imaging.

Optimized Partial Field-of-View Reconstruction by Limited TOF Axial Rebinning in Long-Axial PET (#2235)

Inki Hong, Ziad Burbar

Siemens Healthineers, R&D, Knoxville, USA

Abstract

This work addresses efficient partial axial field-of-view (aFoV) reconstruction for long-axial PET systems, where reconstructing the full long-axial dataset and subsequently cropping to a target aFoV is computationally expensive. This need may arise when CT coverage is intentionally limited (e.g., organ-focused protocols or pediatric imaging). However, simply limiting the PET aFoV reduces the effective sensitivity of a long-aFoV scanner to that of a shorter-aFoV system. We propose a limited axial rebinning strategy that retains a subset of oblique lines of response that would otherwise be discarded when truncating data to a partial aFoV, thereby leveraging the sensitivity of the long-aFoV system. The approach selects a starting rebin segment and a bounded set of additional oblique segments (up to a maximum rebin segment), and rebins eligible events into target segments while preserving time-of-flight (TOF) geometry. In an FDG human study on a long-aFoV system, the proposed limited rebinning substantially increases retained true counts for a Vision-equivalent aFoV versus truncation without rebinning, while maintaining comparable axial resolution and avoiding the cost of reconstructing the full long-aFoV image.

Abstract
PET/CT radiation exposure arises from both the injected PET radiotracer and the accompanying CT scan used for attenuation and scatter correction. Reducing PET dose while eliminating CT-based correction is therefore an attractive strategy for lower-radiation PET/CT imaging, but this setting substantially degrades image quality. In this study, we propose a deep learning framework for CT-free low-dose [18F]FDG PET restoration based on a Noise-Level-Estimation network and systematically evaluate its generalizability across different PET scanners. The model restores attenuation- and scatter-corrected PET images from reduced-dose non-corrected inputs using a mixed-dose training strategy. It was trained on a main cohort from Ruijin Hospital, acquired with [18F]FDG on a

uEXPLORER scanner, comprising 5,731 reconstructed PET volumes derived from 1,163 examinations. Scanner-domain validation was performed on 640 reconstructed PET volumes derived from 320 examinations acquired on three different scanners, including Discovery MI, Vision 450, and uMI 780. Direct pretrained inference, few-shot scanner-domain finetuning, and from-scratch training were compared. Direct application of the uEXPLORER-trained model showed performance degradation under scanner shifts, whereas few-shot finetuning consistently improved restoration fidelity. In the most challenging uMI 780 cohort, median PSNR increased from 35.24 dB to 47.58 dB after finetuning. These results demonstrate the feasibility of scanner-generalizable CT-free low-dose FDG PET restoration.

Abstract
Neural Network (NN) models have emerged as a promising tool for determining 3D photon impact positions in Positron Emission Tomography (PET) detectors based on monolithic scintillators. Nevertheless, NNs typically require long acquisitions of reference data training, becoming a time-consuming process that requires extensive experimental data for each individual detector module. To reduce calibration time, we propose a new methodology based on NNs trained entirely using simulated data to predict the 3D impact position of gamma rays. The feasibility of the proposed approach was verified using a real preclinical PET system composed of two rings of 8 LYSO:Ce monolithic scintillators each.

The simulation of a single detector was implemented in GATE and reference data moving a pencil beam in 1 mm steps was simulated to train two Multilayer Perceptrons (MLPs), MLP_X and MLP_Y, to predict the *x*- and *y*- impact positions, respectively. To validate the introduced methodology at reconstructed image level, experimental data was acquired using a ^{22}Na point source at the center of the preclinical system and processed using both the presented framework and the system's standard calibration methodology.
Results have demonstrated that similar spatial resolution was obtained with both approaches, thus demonstrating that NNs trained exclusively with Monte Carlo simulations can generate coherent reconstructed images and thus eliminate the need for calibration measurements for each individual detector module.

Depth Attention and Volume Attention Module for 3D Medical Image Segmentation (#1088)

Xiaoshuo Kan[1], Koichi Ogawa[2]

[1] Hosei University, Graduate School of Science and Engineering, Tokyo, Japan; [2] Hosei University, Faculty of Science and Engineering, Tokyo, Japan

Abstract
3D medical image segmentation of CT and MRI volumes is essential for clinical diagnosis and treatment planning. While deep learning methods such as 3D U-Net, Attention U-Net, and nnU-Net achieve strong performance, conventional 3D CNNs treat all slices equally along the axial direction, causing insufficient learning of lesion-containing slices. Existing attention mechanisms such as Attention U-Net focus on height×width (H×W) planar spatial attention without explicitly modeling slice-wise importance along the depth (D) axis. This paper proposes two attention modules to address these limitations. First, a Depth Attention Module (DAM) automatically learns the importance of each slice and integrates it into each decoder layer via residual connection. Second, a volume Attention Module (VAM) extends DAM to independently learn importance along H, W, and D axes, combining three independent axis-wise attention maps to achieve disease-adaptive spatial importance learning. DAM achieves Dice improvements of 7.61%, 4.71%, and 3.72% over 3D U-Net on brain hemorrhage CT (HemSeg-200), kidney CT, and ischemic stroke MRI, respectively, and 8.52% over nnU-Net on lung cancer CT (MSD Task06). On brain hemorrhage CT, DAM further improves over Attention U-Net by 4.54% and over nnU-Net by 1.03%. VAM achieves improvements of 7.76% over 3D U-Net on brain hemorrhage CT and 2.83% over nnU-Net on lung cancer CT. Experimental results confirm the effectiveness of the proposed modules across multiple diseases and imaging modalities.

Comparing the anatomical accuracy of a PET(O15) reconstructed algorithm (AGR) on Moyamoya Patients (#1252)

Azeezat Azeez[1], Andrew Zhang[1], Moss Zhao[2], Greg Zaharchuk[1], Fernando Boada[1]

[1] Stanford School of Medicine, Radiological Sciences Laboratory, Palo Alto, USA; [2] Stanford School of Medicine, Department of Neurosurgery, Palo Alto, USA

Abstract

PET(O15) is the gold standard for assessing cerebral perfusion in vivo. Assessment of perfusion deficits before surgical interventions in Moyamoya patients with PET(O15) is hampered by poor spatial resolution and low signal-to-noise ratio (SNR). We investigate the use of anatomically-guided reconstruction (AGR) for improving the assessment of baseline perfusion metrics in Moyamoya patients. To evaluate PET(O15) perfusion metrics in Moyamoya patients with and without the use of anatomically guided reconstructions. We assess perfusion metrics across different anatomical brain parcellations to evaluate the differences between the conventional and AGR-enhanced PET(O15) images. Regions that overlap with clinically relevant regions are significantly different in signal intensity when comparing the use of the reconstruction method. Many of which overlap with those reported in the Moyamoya literature. Implementation of the anatomy-guided PET reconstruction(AGR) algorithm can provide clinicians with a better understanding of the disease progression, especially if data integrity is limited, and of low resolution. Particularly in cases of radioisotopes with short decay half-life, such as O15, or when studying diseases of tissue perfusion and oxygen metabolism.

Abstract

Spatial normalization enables standardized volume-of-interest quantification in brain perfusion single-photon emission computed tomography, but accurate alignment is difficult because of low resolution, noise, partial volume effects, and uptake-dependent variation. We propose a MRI-informed, SPECT-only framework that distills anatomical deformation fields and feature guidance from a magnetic resonance imaging registration teacher. The student disentangles anatomical and uptake-related representations to suppress functional-uptake interference while requiring only single-photon emission computed tomography at inference. In 173 paired imaging datasets, the method improved standardized uptake value ratio consistency between subject and template spaces, especially for fine-grained volumes of interest, supporting MRI-free, single-pass template-based quantification.

When Do TAC and ROI Features Help? Residual Multimodal Learning for GFR Estimation in Dynamic ^{99m}Tc-DTPA Renography (#1697)

Yuanhao Zhu[1], Jinlin Li[2], Chunhao Li[1], Jiaqi Zhong[2], Wen Sun[2], Zhuoyuan Xu[1], Jingxian Chen[3], Yuecan Zeng[4], Jingzhang Sun[1], Huan Xiao[2]

Abstract

Dynamic ^{99m}Tc-DTPA renography provides both spatiotemporal image information and clinically interpretable time-activity curve (TAC) and region-of-interest (ROI) descriptors for renal functional assessment. However, how these heterogeneous information sources should be integrated for automated Gates-derived total glomerular filtration rate (GFR) estimation remains unclear. This study developed a residual multimodal learning framework in which a 3D CNN image branch first estimated Gates-derived total GFR from multi-frame renography sequences, and selected TAC/ROI descriptors were then used to predict a residual correction term rather than being directly concatenated with image features. A total of 471 complete paired examinations were retrospectively included, with 376 cases for training and 95 cases for held-out testing. Representative image-only, TAC-only, direct-fusion, ROI/TAC tabular, and residual-correction models were compared under the same test split. The dynamic image-only model outperformed perfusion TAC-only, function TAC-only, and pure ROI/TAC tabular models, indicating that the multi-frame renography sequence was the dominant information source. Direct fusion of image and TAC inputs did not improve image-only prediction. In contrast, the proposed residual-correction model achieved the best overall performance, with the lowest mean absolute error of 8.21 and root mean square error of 10.93. These findings suggest that TAC/ROI descriptors are more useful as clinically interpretable residual correction cues than as standalone predictors or directly fused inputs. The proposed framework provides a practical strategy for approximating total GFR from routine dynamic ^{99m}Tc-DTPA renography while clarifying the complementary role of TAC/ROI descriptors.

Uncertainty-Guided Localized Diffusion Refinement for Lumbar Spine MRI Segmentation (#1924)

Quang Vinh Pham[1,2], Saerom Sung[1], Hyun Joon Choi[3], Sangwoon Jeong[3], Seoung Wan Nam[4], Hyunjung Kim[5], Chul Hee Min[1]

[1] Yonsei University, Department of Radiation Convergence Engineering, Wonju, South Korea; [2] Hanoi University of Science and Technology, Faculty of Engineering Physics, Hanoi, Vietnam; [3] Yonsei University Wonju College of Medicine, Department of Radiation Oncology, Wonju, South Korea; [4] Wonju Severance Christian Hospital, Wonju College of Medicine, Yonsei University, Department of Rheumatology, Wonju, South Korea; [5] Wonju Severance Christian Hospital, Wonju College of Medicine, Yonsei University, Department of Radiology, Wonju, South Korea

Abstract

Lumbar spine MRI segmentation is an important prerequisite for quantitative spine image analysis; however, it remains challenging due to complex anatomy, low contrast, and high inter-patient variability. Recent diffusion-based approaches have shown potential for medical image segmentation; nevertheless, preserving anatomically consistent boundaries remains challenging, particularly in low-contrast regions. We propose a conditional diffusion-based framework for lumbar spine MRI segmentation with uncertainty-guided localized refinement. The model integrates a UNet-based denoising backbone with multi-scale feature encoding to preserve anatomical structures during the diffusion process. Furthermore, an entropy-driven uncertainty mechanism is introduced to identify ambiguous regions, enabling localized refinement and selective diffusion re-sampling in low-confidence regions to support boundary delineation. The framework is evaluated using 5-fold cross-validation on multi-contrast (T1- and T2-weighted) MRI data, achieving Dice scores of 0.87-0.89 with low surface errors (ASSD ≈ 1-2 mm, HD95 < 10 mm). The current results demonstrate consistent segmentation performance across spinal canal, vertebral bodies, and intervertebral discs, indicating the feasibility of automated multi-structure lumbar MRI segmentation. These results suggest that the proposed framework can serve as a technical foundation for automated quantitative spine MRI analysis. In future work, this framework will be extended to vertebral body and corner-region analysis for edema detection, assessment of corner changes, and quantitative MRI evaluation of axial spondyloarthritis.

Abstract

Total-body positron emission tomography (PET) increases system sensitivity and enables whole-body dynamic imaging, but its extended axial field of view makes accurate depth-of-interaction (DOI) calibration essential for maintaining uniform spatial resolution and reducing parallax error. Conventional DOI calibration requires mechanically scanned collimated sources or detector-specific reference measurements, which become impractical as the number of detector modules increases. PhysiCal-PET introduces a physics-based neural-network framework for autonomous in-system DOI calibration of PET scanners. The method trains a network to map raw detector signals to DOI using coincidence data acquired with an uncollimated positron source at known positions. For each event, the loss function enforces annihilation geometry by requiring the predicted line of response to be consistent with the source position, thereby providing supervision without measured DOI labels. The framework was tested on realistic PET simulations and applied to data from a real preclinical PET scanner. Using this procedure, the DOI response of all 144 detector modules was calibrated in less than 2 hours of point-source measurement time. These results demonstrate that the annihilation physics can replace labor-intensive DOI calibration hardware and enable rapid, routine calibration of high-resolution PET systems. PhysiCal-PET therefore provides a scalable path toward autonomous calibration for total-body PET and other systems that rely on accurate DOI positioning. notionvc: 49ace5df-389b-489a-b611-1abe67c4c114

Nonsubsampled Contourlet Transform-based Generative Adversarial Networks for Anatomical Structure-Preserving Low Dose CT Denoising

(#2204)

Hyosung Cho, **Sanghyun Cho**

Yonsei University, Department of Radiation Convergence Engineering, Wonju, South Korea

This work was supported by the National Research Foundation of Korea(NRF) grant funded by the Korea government(MSIT)(RS-2025-16065119).

Abstract

This paper presents a Nonsubsampled Contourlet Transform-Based Generative Adversarial Network (NSCT-GAN) for low-dose computed tomography (LDCT) denoising. LDCT reduces radiation exposure but introduces quantum Poisson and electronic Gaussian noise, which blurs anatomical structures. Conventional deep learning methods using mean-squared error loss produce over-smoothed images, while existing image-domain generative adversarial networks (GANs) struggle with high-frequency CT noise. To address this, the proposed NSCT-GAN extracts multi-scale, multi-directional, and shift-invariant high-frequency features using the NSCT. The network trains a discriminator on these high-frequency images to distinguish noise from anatomical edges. The generator utilizes a U-Net architecture to maintain spatial consistency. The objective function combines a Wasserstein GAN with gradient penalty adversarial loss for high-frequency reconstruction, an L1 loss for accurate CT number recovery, and a multi-scale structural similarity (MS-SSIM) loss for global and local structural consistency. The method was evaluated using the 2016 NIH-AAPM-Mayo Clinic Low-Dose CT Grand Challenge dataset and compared against five deep learning-based denoising methods: WavResNet, SMGAN, CPCE, DU-GAN, and WDLP. Quantitative results demonstrate that NSCT-GAN achieves a peak signal-to-noise ratio (PSNR) of 27.1850 dB, a structural similarity index (SSIM) of 0.8215, and a feature similarity index (FSIM) of 0.9698, yielding the highest SSIM and FSIM values among the tested models. Qualitative evaluations show the method restores continuous vascular boundaries in the lungs and maintains heterogeneous parenchymal patterns in the liver without introducing over-smoothing or artifacts.

Preliminary Results of Generative Model-Based Positron Range Correction in PET Imaging (#2359)

Yucun Hou[1], Jiaru Ni[1], Yihao Chen[1], Fenglin Zhan[2,3], Jianyong Jiang[1]

[1] Beijing Normal University, School of Physics and Astronomy, Beijing, China; [2] The First Affiliated Hospital of USTC, Department of Nuclear Medicine, Hefei, China; [3] Jiangnan University, Wuxi School of Medicine, Wuxi, China

This work was supported in part by the National Natural Science Foundation of China (No. 12475336), and the Fundamental Research Funds for the Central Universities (No. 310400209521).

Abstract

Positron range is an inherent physical factor that degrades the spatial resolution of positron emission tomography (PET), particularly for radionuclides with high positron energies. This study investigated the feasibility of deep learning-based positron range correction for PET brain imaging. A total of 304 brain datasets acquired using a Siemens Biograph Vision PET/CT scanner at the First Affiliated Hospital of the University of Science and Technology of China were voxelized to generate brain phantoms. These phantoms were used as activity maps for GATE simulations with three emission settings: ^{18}F, ^{68}Ga, and back-to-back sources. The ^{18}F and ^{68}Ga simulations represented mild and severe positron range effects, respectively, whereas the back-to-back simulation served as the range-free reference. Two deep learning-based correction methods were evaluated, including a conditional denoising diffusion probabilistic model (C-DDPM) and a residual U-Net (Res-UNet). Visual results showed that C-DDPM better restored fine sulcal and gyral structures and achieved closer agreement with the back-to-back reference, especially for the more severe ^{68}Ga correction task. Although Res-UNet achieved superior PSNR, SSIM, and NRMSE values, its restored images exhibited noticeable oversmoothing and partial loss of subtle anatomical details. These findings suggest that diffusion-based generative restoration is a promising strategy for positron range correction, with the potential to reduce positron range induced blurring while preserving fine anatomical structures.

Wavelet-Conditioned Rectified Flow for Efficient Whole-Body Low-Dose PET Denoising (#2431)

Luxiang Xie, Weigang Duan, Jiali Yan, Hongyang Zhang, Shi Wang, Zhaoxia Wu, Hui Liu, Yaqiang Liu

Tsinghua University, Beijing, China

The authors gratefully acknowledge Xue Song, Kuangyu Shi, and Axel Rominger from the University of Bern, as well as Hanzhong Wang, Rui Guo, and Biao Li from Ruijin Hospital, Shanghai Jiao Tong University School of Medicine, for providing the PET data used in this study.

Abstract

Low-dose positron emission tomography (PET) reduces injected activity and acquisition time, but low-count statistics introduce strong noise, impaired lesion conspicuity, and unstable standardized uptake value (SUV) quantification in whole-body imaging. Recent 3D diffusion models improve PET denoising, and wavelet-conditioned diffusion further shows that the Haar low-frequency LLL subband can serve as a robust structural prior. However, diffusion sampling is computationally expensive for large 3D PET volumes. We propose Wavelet-Conditioned Rectified Flow (WCRF), a deterministic whole-body PET restoration framework that integrates wavelet-domain structural guidance with rectified-flow matching.To establish robust structural guidance, WCRF isolates the lowest-frequency (LLL) subband via a single-level 3D Haar decomposition. This frequency-derived information is then combined with the original noisy input to form a resilient conditioning signal. A lightweight ControlNet-style branch injects this condition into a time-conditioned rectified-flow network, which learns the velocity field from low-dose to full-dose PET along a straight transport path. During inference, WCRF restores full 3D volumes using sliding-window Euler integration with only a small number of function evaluations. Experiments against low-dose input, 3D U-Net, 3D GAN, and 3D DDPM baselines at the 1/20-dose setting show that WCRF achieves competitive overall restoration performance among the evaluated methods, while substantially reducing inference cost relative to DDPM.

Abstract

A spatio-temporal denoising training strategy for low-dose fluoroscopy is proposed, based on a spatially-adaptive temporal consistency metric. This approach acts on a small set of consecutive frames coupling a conventional denoising operator with an adaptive motion-gradient attention gate to selectively modulate the temporal consistency terms within the loss function, ensuring effective noise suppression and flickering reduction while maintaining high anatomical fidelity in dynamic regions.
The proposed method was used to train a denoising operator in which a three-frame temporal window is used as input. The model was trained across multiple dose reduction factors (qF), and demonstrated superior structural recovery and enhanced temporal stability in the processed image sequences, compared to single-frame models. Quantitative and qualitative evaluation of image quality, along with stability maps—defined as the Normalized Cross-Correlation (NCC) of temporal Coefficient of Variation (CV) maps—confirms high fidelity relative to high-dose reference acquisitions, effectively mitigating stochastic fluctuations without introducing motion artifacts.

Abstract

Carbon-ion radiotherapy (CIRT) combines high biological effectiveness with outstanding treatment precision. Since treatment plans are based on the most recent Computed Tomography (CT), anatomical changes during multi-week treatments may compromise dose delivery accuracy. To address the increasing uncertainty about the patient's anatomical state with time elapsed since the planning CT, our group developed an in vivo monitoring method using secondary charged particles emitted during therapy. This non-invasive approach requires no additional dose and reduces uncertainty about patient anatomy and thus, loss of treatment accuracy. It uses a custom detection system to detect nuclear fragments emmited from the patient and allows approximating their origin. To reconstruct these changes in 3D, we utilize our recently published method for detecting the depth (z) of changes along the beam axis and apply it to a sliding window (x,y) along the transverse plane. However, splitting reconstructed nuclear fragment origins into smaller subsets reduces the statistical stability of each subset distribution. In this study, we present an approach to robustly distinguish whether a windowed subset belongs to a region with or without an anatomical change based on correlation matrices generated by our depth detection method. These images contain location-wise correlations of joined frequency band variations between projections of nuclear fragment measurements from different treatment days. To classify regions of change and approximate change depth, we train an ensemble of deep learning-based image classifiers with different architectures *(i.e. ResNet, RegNet and ConvNeXt)* and combine their outputs into an ensemble decision. The approach was validated using dedicated irradiation measurements with coin-sized cavities inserted into PMMA head phantoms. Despite limited training data, we achieved robust improvements in change localization using an ensemble of different deep learning architectures.

Abstract

Despite its widespread use for compensating attenuation in positron emission tomography (PET), computed tomography (CT)-based attenuation correction has limitations which can create imaging artifacts associated with breathing motion and metallic implants. Using deep learning networks to create synthetic attenuation correction maps represents a data-driven, non-ionizing alternative with the potential to reduce the frequency and/or intensity of such errors. In this study, the authors aimed to demonstrate that using synthetic maps would reduce breathing motion and metallic implant artifacts. To achieve this, ten anonymized whole-body F^{18}-Fluorodeoxyglucose exams were assessed. Scans were divided into two Cohorts; Cohort 1 comprised exams with breathing motion artifacts, whilst Cohort 2 contained scans of patients with hip replacements. Each scan was corrected separately with CT-based attenuation correction and synthetic maps prior to identical reconstruction. Quantitative assessments of standardized uptake value (SUV) parameters were performed, and differences were tested for statistical significance. Additionally, each image's lesion detectability, diagnostic confidence and overall image quality were scored on a Likert scale by an experienced radiologist. After assessment, no statistically significant differences in SUV quantification were detected ($p > 0.05$). Images corrected with synthetic maps were preferred by the radiologist in Cohort 1, but no preference was expressed in Cohort 2. Moreover, a single Cohort 1 case was identified in which breathing motion artifacts impacted clinical diagnosis only for the image treated with CT-based attenuation correction. Thus, it was concluded that synthetic maps reduce breathing motion artifacts to an extent which may support clinical diagnoses, although their effects on metallic implant artifacts require further investigation.

Frozen Stable Diffusion VAE as a Slice-Wise Encoder for Scalable 3-D Medical Image Generation (#2828)

Youness Mellak, Antoine De Paepe, Alexandre Bousse, Dimitris Visvikis

Université de Bretagne Occidentale, LaTIM, INSERM, UMR 1101, Brest, France

Abstract

Full-volume 3-D medical image generation at clinical resolutions remains a significant challenge due to GPU memory constraints. Existing voxel-space generative methods are difficult to scale to large clinical volumes, as memory and compute costs grow rapidly with spatial resolution. Latent diffusion approaches offer a more scalable alternative [1], but they typically require training a dedicated medical autoencoder for each modality or dataset before generative modeling can begin, making the compression stage itself a major bottleneck [2], [3], [4]. A lighter alternative is to encode axial slices independently with a 2-D autoencoder and stack the resulting latent maps into a 3-D tensor [5]; however, this still requires training a modality-specific encoder from scratch, limiting generality across modalities and resolutions.

We propose a scalable latent flow framework that eliminates this bottleneck by using a frozen pretrained Stable Diffusion VAE as a ready-to-use slice-wise encoder for medical volumes, requiring no modality-specific retraining or adaptation. Each axial slice is resampled to a common resolution, intensity-normalized, and encoded independently by the frozen encoder, yielding a high in-plane compression factor compared to dedicated medical autoencoders. The resulting latent maps are stacked into a compact 3-D tensor, on which a full-volume 3-D U-Net flow model is trained directly. The objective predicts clean latents and supervises in velocity space [6], ensuring stable optimization and sharp generations in high-dimensional latent spaces, avoiding the blurriness and instability observed with standard diffusion objectives.

We validate our framework on CT, PET, and MRI volumes at clinical resolutions, demonstrating strong encoding fidelity and coherent full-volume generation across axial, coronal, and sagittal planes on a single consumer-grade GPU, without any modality-specific autoencoder training.

Deep learning-based 3D SPECT generation model for 225Ac-DOTATATE quantification using CT and 2D Planar images (#2434)

Jingyu Yang[1], Muath Almaslamani[1,2], Inki Lee[3], Ilhan Lim[3], Sang-Keun Woo[1,2]

[1] Korea Institute of Radiological and Medical Sciences, Division of Applied RI, Seoul, South Korea; [2] University of Science & Technology, Radiological & Medico-Oncological Sciences, Daejeon, South Korea; [3] Korea Institute of Radiological and Medical Sciences, Department of Nuclear Medicine, Seoul, South Korea

Abstract

Targeted alpha therapy using ^{225}Ac-DOTATATE has shown promise for patients with metastatic or inoperable neuroendocrine tumors. Image-based dosimetry is important for treatment optimization and toxicity assessment; however, quantitative ^{225}Ac SPECT imaging is challenging due to low injected activity and limited gamma-ray count statistics. This study aimed to investigate the feasibility of generating ^{225}Ac-DOTATATE SPECT images from planar and CT images using a deep learning-based image generation framework. Five patients were administrated administered with 205 μCi of ^{225}Ac-DOTATATE were included. Planar, SPECT and CT imaging was performed 24 h after administration using a dual-head Symbia T2 scanner with energy windows centered at 78, 218, and 440 keV. Fusion images were generated from planar and CT images using the conjugate view method described in MIRD Pamphlet No. 16. Planar images, fusion images, and CT images were used as multimodal inputs to a 3D U-Net encoder–decoder network to generate quantitative SPECT images. All images were resized to 128 × 128 × 128 voxels and normalized. The model was optimized using the Adam optimizer with a learning rate of 2×10^{-5}, batch size of 1, and 500 epochs, using L1 loss. The generated SPECT images showed uptake patterns comparable to acquired SPECT images. Quantitative organ-level analysis showed similar uptake distributions across major organs and tumor regions, with relative uptake error below 15% in most organs. These findings demonstrate the feasibility of planar-to-SPECT image generation using deep learning and suggest its potential to support ^{225}Ac-DOTATATE image-based dosimetry by providing three-dimensional radiopharmaceutical distribution from clinically practical planar and CT images.

[1] Universidad Carlos III de Madrid, Dpt. Bioengineering, Madrid, Spain; [2] Instituto de Investigación Sanitaria Gregorio Marañón, Madrid, Spain; [3] Massachusetts General Hospital, Harvard Medical School, Dpt. Radiology, Boston, USA; [4] Massachusetts Institute of Technology, Cambridge, USA

Abstract

Dedicated standalone brain positron emission tomography (PET) scanners have emerged in recent years as a promising technology for neuroimaging, offering high spatial resolution, increased sensitivity, reduced injected dose and shorter acquisition times. However, unlike hybrid PET/computed tomography (PET/CT) or PET/magnetic resonance imaging (PET/MRI) systems, these scanners do not provide an anatomical image from which attenuation information can be derived. We present a SynthSR-based framework to predict CT-derived attenuation maps from non-attenuation-corrected (NAC) PET images, aiming to enable attenuation correction in standalone brain PET. Building on SynthSR, a large and widely variable set of synthetic PET volumes is generated to sample a space larger than the potential clinically viable PET images, and thus increasing the robustness and clinical applicability of the model. The synthetic PET volumes are generated on-the-fly from anatomical labels using label-conditioned Gaussian-mixture intensity sampling, spatial/intensity augmentation and PET-specific priors estimated from real normalized PET data. A PET appearance model introduces count-based noise, correlated texture, smoothing, and controlled intensity variability. Finally, spatial transformations are used to increase sample diversity while preserving voxel-wise alignment. A three-dimensional U-Net was trained to predict normalized attenuation maps from synthetic PET, while validation and testing were performed on never-seen real PET/CT data. The model was optimized with 24,000 on-the-fly synthetic samples and evaluated on held-out real PET/CT data. The best validation checkpoint achieved MAE=0.03 (3%), PSNR=25.74 dB, and Pearson correlation r=0.859. On the independent test subject, the model achieved MAE=0.027 (2.7%), PSNR=26.35 dB, and r=0.854. These results support the feasibility of CT/MRI naive pseudo-CT generation for PET attenuation correction in novel standalone dedicated brain PET scanners.

Abstract

Targeted Alpha Therapy with actinium-225 induces double-strand DNA breaks through individual alpha decays, motivating quantitative imaging of single-event distributions for dose assessment. We address point detection in a cerium-doped gadolinium aluminum gallium garnet scintillator coupled to an electron-multiplying camera, in which each alpha produces a point-spread function of approximately 2-micrometer diameter at 10 to 150 events per 100-millisecond frame. We compare three method groups on Monte Carlo simulated images: 20 classical preprocessing-and-clustering pipelines, two deep learning detectors based on the U-Net and YOLOv8-nano architectures, and Alpha-CenterNet, a heatmap-based detector that adapts CenterNet with a feature pyramid network and a modified focal loss. The highest-F1 classical pipeline attains 0.641 with 447-nanometer mean localization error. U-Net reaches F1 = 0.978 with 302-nanometer error; YOLOv8-nano reaches 185-nanometer error with F1 = 0.938; the two metrics produce divergent rankings. Alpha-CenterNet (3.78 million parameters) achieves F1 = 0.965 and 244-nanometer error, reducing localization error by 19 percent relative to U-Net at 26 percent of its parameter count, and reaching the validation F1 plateau of 0.98 in 29 versus 86 epochs—a 2.97-fold convergence speedup within the same ablation. The modified focal loss decouples F1 from localization error: F1 changes by 0.0004 while the mean error decreases by 76 nanometers, and this effect persists across all tested densities. The method generalizes to clustered and edge source distributions at unseen densities, supporting point detection for Targeted Alpha Therapy monitoring.

Abstract

Artificial-intelligence-assisted PCB layout is an emerging capability that promises to reduce design iteration time and enable rapid exploration of placement and routing alternatives, which is particularly valuable for complex, multi-channel analog front-end boards where manual layout is labor-intensive and experience-dependent. In this work, we explore the application of an AI-assisted layout workflow to a timing-sensitive silicon photomultiplier (SiPM) front-end readout board for time-of-flight positron emission tomography (TOF-PET) detectors. A four-channel RF front-end readout board, extending a validated single-channel timing topology, underwent automated placement and routing via AI layout tools. To establish a performance baseline, a single-channel prototype of the same RF topology was fabricated and characterized using a coincidence measurement setup with LYSO scintillators, achieving a coincidence time resolution of 100.78 ps and confirming the near-100-ps timing capability of the front-end design. Preliminary evaluation of the AI-generated four-channel layout shows that the tool achieved high routing completion and produced a viable candidate layout. Based on these encouraging results, we plan to fabricate the AI-generated board and systematically compare its timing performance, energy response, and channel consistency against our manually designed baseline, providing a direct, measurement-level assessment of AI-assisted layout quality for timing-sensitive detector electronics.

Abstract

Simultaneous dual tracer PET provides complementary physiological information compared with single tracer imaging. For example, combining [^{89}Zr]labeled monoclonal antibodies (mAbs) with [^{18}F]fluorodeoxyglucose (FDG) enables the assessment of both targeted uptake and glucose metabolism, potentially improving patient selection [1]. Existing dual tracer separation methods exploiting differences in tracer kinetics are typically applied post-reconstruction in the image domain. However, these approaches may be sensitive to noise propagation. In this work, we evaluate a sinogram-domain iterative separation method that is incorporated directly into the reconstruction process, enabling direct generation of single tracer images.

High-Energy Proton Scattering Radiography of a Geant4 Hand Phantom under Constant-Energy Loss (#1435)

Reshma S. Ughade, Stylianos Chatzidakis

Purdue University, West Lafayette, USA

The present research is being conducted with the support of funding provided by the Purdue University School of Nuclear Engineering and the Purdue Research Foundation.

Abstract

Proton radiography and tomography often use residual energy or water equivalent path length (WEPL) to estimate relative stopping power (RSP). Since the maximum likelihood path (MLP) formalism of Schulte et al. (2008), proton trajectories in tissue have been modeled as curved paths constrained by entry and exit tracking. In full proton CT, this path estimation is coupled to energy dependent multiple Coulomb scattering and longitudinal energy loss, which becomes computationally and physically complex at low residual energies. Most MLP based reconstructions use the estimated path mainly to assign WEPL or RSP contributions to voxels. Here, we examine a thin object regime in which scattering itself provides imaging contrast. For high energy protons traversing a human hand, the integrated energy loss is small, allowing the scattering relevant βcp factor to be approximated as constant along the path. Under this constant energy approximation, we reconstruct a volumetric scattering density map using an M-value calculated from each proton scattering angle and kinetic energy, together with the μTRec Bayesian voxel attribution algorithm developed for muon scattering tomography. The method is demonstrated in Geant4 using an anthropomorphic hand phantom containing bones, muscles, tendons, and skin. A single orientation 200 MeV parallel proton beam with 10^7 protons is simulated and reconstructed on a 0.3 mm voxel grid. The resulting proton radiograph resolves carpals, metacarpals, and phalanges, and detects a submillimetre osteochondral gap at the thumb interphalangeal joint. These results suggest that constant energy, MLP inspired scattering radiography can provide a computationally lightweight alternative or complement to energy loss based proton imaging for thin anatomical sites.

Abstract

The growing importance of theranostics and research with long-lived isotopes demands imaging systems far more sensitive than standard PET or SPECT. Many emerging isotopes lie outside current detector capabilities, resulting in low sensitivity, high background, and poor quantification, as seen with ^{90}Y verification and ^{124}I or ^{89}Sr imaging. The Multiple Emission Tomography (MET) project introduces a novel imaging device based on inorganic scintillators, capable of operating in dual modes: PET-style coincidence detection of 511 keV photon pairs and single-photon Compton-scattering detection in a single-layer configuration. The technical configuration of the MET prototype utilizes a DOI-capable light-sharing scheme. Each module consists of a 16x16 matrix of 1.53x1.53x20 mm^3 depolished LYSO crystals coupled to an 8x8 array of 3x3 mm^2 Hamamatsu Silicon Photomultipliers (SiPMs). The detector's readout electronics are based on the ALCOR ASIC, a low-power, mixed-signal device featuring single-photon sensitivity, a high bandwidth of up to 2 Mevents/s per channel, and a fine 25 ps time binning. Supported by a combination of analytic algorithms and a machine learning pipeline, the MET detector can successfully solve the temporal sequence of inter-crystal scatters, and determine the points of interaction and the energies deposited. To fully leverage these recovered events, a dedicated Compton image reconstruction algorithm has been developed, employing an event-by-event statistical model with ad-hoc projector functions. This technology is expected to significantly impact theranostics, collimator-less SPECT, and in-vivo range verification for CPT.

Abstract

Gold and gadolinium-based nanoparticles have been investigated as theranostic agents whose characteristic X-ray fluorescence (XRF) emissions enable non-invasive, element-specific biodistribution imaging. This work presents the design, assembly, and characterization of a scalable NaI(Tl)-SiPM scintillation detector module developed as a building block for a 16-element detector array for the Confocal Orthovoltage X-Ray--Induced Radiation System (COXIRIS) Project. Each module comprises a 25.4x25.4x4 mm^3 monolithic NaI(Tl) crystal optically coupled to a custom SiPM array and read out by the TOFPET2 ASIC.

The architecture targets the K-shell fluorescence lines of gold ($K\alpha$ = 68 keV) and gadolinium ($K\alpha$ = 43 keV), while providing a large active area at low cost.

Four modules were characterized with a 2.0 μCi ^{241}Am source, whose 59.5 keV emission lies within the 40--80 keV target interval. The peak was clearly identified in all modules, with energy resolutions ranging from 47% to 65%. Per-pixel gain calibration produced an additional relative improvement of approximately 2% for each module. These results support the feasibility of the proposed assembly approach as a detector building block for XRF imaging applications.

Abstract

Positron emission tomography (PET) is traditionally limited to scanning one tracer per session. Positron and prompt gamma emitters may be used to form triple coincidences that allow for signal separation based on energy. We present a proof-of-concept, preclinical PET system designed for detecting and distinguishing prompt gamma and annihilation photons in the same detector. We describe the data processing pipeline with advances for estimating randoms, scatter, and sensitivity of the prompt gamma photon. System performance is characterized with NEMA and Derenzo phantom studies. Next, we present multi-isotope studies using ^{52}Mn and ^{18}F in a custom image quality phantom. We compare two reconstruction methods and find alternating updates yield faster convergence and higher image quality. After correcting for injected activity and decay, the mean voxel intensity ratio between ^{18}F and ^{52}Mn across background ROIs is 0.95 ± 0.06, where 1 represents perfect quantitative agreement. The uncertainty reflects variability across ROIs and dose calibrator uncertainty (±2%), suggesting unmixing accuracy is within dose calibrator tolerance. Further, we scan the phantom after ^{18}F decay to determine the relative image quality between single (^{52}Mn only) and dual (^{52}Mn with ^{18}F) acquisition. We find the ^{52}Mn image has similar contrast recovery (0.65/0.62) and crosstalk ratio (0.24/0.24) between the single and dual acquisition. Due to low triples sensitivity, simultaneous acquisition of both radionuclides reduces the contrast to noise from 10.2 to 4.7. Despite limitations on axial field of view, data rate, and the high background from ^{52}Mn's 3 gamma cascade, we achieve high quantitative accuracy. Future studies will scale up the system, use more favorable tracers, add regularization to mitigate noise propagation and include preclinical animal scans.

On the Pseudo Dark-Field Signal in X-Ray Scattering Tensor Tomography (#2316)

Runtao Deng, Ruifeng Liu, Peixuan Song, Jincheng Lu, Li Zhang, Zhentian Wang

Tsinghua University, Department of Engineering Physics, Beijing, China

Abstract

X-ray scattering tensor tomography retrieves directional dark-field projections from the focused, structured illumination produced by 2D diffractive optics, and is increasingly attractive as a route to anisotropic micro-structural imaging on laboratory sources. Quantitative tensor reconstruction requires the focused reference field to cancel out exactly in the Fourier-domain retrieval, a condition met only under monochromatic illumination. We show that beam hardening through an absorbing sample reshapes this focused reference field non-uniformly across its bright core and the surrounding plateau, so the retrieval assigns a non-zero scattering tensor to a purely absorbing object—a pseudo dark-field signal. We derive a closed-form expression for the pseudo dark-field signal, prove its exact isotropy arising from the circular symmetry of the focal spot, and identify the retrieved observables that are biased by beam hardening versus those that are not. The standard angular-consistency metric is blind to this bias, so a dedicated calibration is required. We describe a step-wedge calibration protocol that compresses the family of pseudo dark-field signals into a single thickness-dependent function suitable for per-pixel correction. Removing this artefact is a prerequisite for quantitative X-ray scattering tensor tomography on laboratory sources.

Abstract

Simultaneous dual-radionuclide imaging offers complementary information for diagnosis, stratification, treatment planning, and therapy evaluation. However, the fundamental differences between PET and SPECT present significant challenges for integrated imaging. We propose a scintillator-as-collimator detector enabling both PET and SPECT. It consists of three scintillator layers separated by two light guides. Parallel holes in the upper portion function as a SPECT collimator, referred to as the scintillator-as-collimator volume (SCV). The lower portion serves as the SPECT detector (SD). In PET mode, the entire detector acts as a multi-resolution TOF-DOI PET detector. Thus, it serves as a self-collimated SPECT or TOF-DOI PET detector. A dual-panel prototype was developed with rotational acquisitions for PET, SPECT, and simultaneous imaging. SPECT events are selected using flood image mask, maximum SiPM channel energy (Pmax), and DOI-integrated charge (QDC). SPECT resolution reaches ~5 mm. PET performance is preserved, with best SD–SD CTR of 352 ps and two-layer DOI. The introduction of holes has minimal impact on PET detection, enabling high-quality PET images. In simultaneous imaging, a unified timing framework rejects 511 keV down-scatter, and residual artefacts were further mitigated using a 200–240 keV energy window for scatter correction. Phantom experiments validate tri-mode imaging. This detector eliminates external collimators, supports multi-tracer imaging, and offers a cost-effective single-detector-set PET&SPECT system.

This work was supported in part by Shanghai United Imaging Medical Technology Co., Ltd., through its internal research program. The authors gratefully acknowledge the Molecular Imaging team for their technical support and helpful discussions.

Abstract

Diffusion models have shown strong potential for improving PET image quality. However, existing methods based on unconditional pretrained diffusion priors often struggle to balance realism and fidelity, particularly in preserving high-resolution details. To address this issue, we propose MI-ResShift, a zero-shot mutual information-guided diffusion model with residual shifting for PET image super-resolution. MI-ResShift introduces a differentiable local-wise mutual information layer to guide the denoising process using structural information from CT or MRI, enabling robust cross-modal feature alignment in the statistical domain. By combining mutual information guidance with residual shifting, the proposed method enhances PET detail fidelity and robustness while reducing diffusion-based inference to only four steps. Experiments on PET/MR brain datasets demonstrate that MI-ResShift improves image quality over classical interpolation methods and provides an efficient solution for cross-modal PET super-resolution.

Abstract

Coincidence-based imaging with the back-to-back 511 keV photon pairs emitted during positron annihilation enables transmission imaging with reduced quantum noise. Conventional transmission imaging recovers only a single attenuation-related quantity per voxel or pixel. In this work, we extend coincidence-based imaging to simultaneously recover both the total and the Compton-scatter linear attenuation coefficients from a single acquisition, providing a second axis for material identification. Forward-scattered photons collected in coincidence within an analytically defined polar window, obtained by integrating the Klein-Nishina differential cross section over a 20-to-30-degree band, enable direct estimation of the Compton macroscopic cross section, while the idler channel provides the incident count for the total coefficient. We evaluate the approach using Monte Carlo simulations of opposing cadmium zinc telluride panels viewing a water phantom of thickness 2 to 10 millimeters. Idler-normalized transmission was recovered to within 0.1 percent across all thicknesses, while the extracted total and Compton coefficients exhibited 1 to 4 percent absolute error, with the Compton coefficient transitioning from over- to underestimation near 6 millimeters. These deviations arise from logarithmic amplification of small counting errors and from competing air-scatter contamination at thin phantoms and self-attenuation of scattered photons at thicker ones. The results establish that scatter data from coincidence-based annihilation imaging can recover a second material descriptor, motivating further development toward dose-efficient material identification.

Abstract

The development of lightweight radiation shielding materials is of high interest for a broad range of defense, space, and medical applications. In particular, mass-savings are desired in vehicles (ground, naval, and/or aerospace) and as wearable fabrics in high dosage environments such as those encountered in the medical setting. Here we investigate the potential of enhanced shielding via radiation attenuation of nanostructured materials which take advantage of interfacial and nanocrystalline loss processes increase the multiplicity of energy loss mechanisms within the shielding solid. In this work, colloidal metallic nanoparticles grown in an aqueous environment (such as palladium (Pd) and silver (Ag)) with sizes in the 5 - 50 nm range are imbedded in a polymeric matrix material (epoxy or aramid nanofiber (ANF)) to demonstrate photon and electron shielding while maintaining mechanical properties such as strength, durability, and form-factor flexibility. The mechanisms of energy loss at the interfaces of the nanomaterials and overall in the solid are quantified through transport modeling as well as the unorthodox usage of the Transmission Electron Microscope (TEM), in which a focused electron beam and state-of-the-art detector system are utilized to measure the effects of particle interactions within our material system to a near single particle resolution. Therefore, this work encompasses both an investigation of the potential enhancement of radiation attenuation by nanostructured materials while also introducing an innovative nanocomposite material system with manufacturing versatility enabling lightweight, flexible shielding.

Abstract

The Sensing Collimation Imager (SCI) is an ultrasensitive gamma detector that integrates multi-pinhole, coded aperture, and self-collimation imaging into a single compact device, achieving substantially higher sensitivity than conventional gamma cameras. Maximizing the spatial encoding capability of the SCI module requires optimizing the crystal arrangement over a high-dimensional combinatorial design space, which is too large for exhaustive search.

We propose an information-theoretic detector geometry optimization framework that uses the Fisher Information Matrix (FIM) spatial correlation map as a computationally efficient performance metric. The metric requires only computing the FWHM of the FIM column vector (O(n)), avoiding the O(n^3) cost of inverting the FIM for the Cramér–Rao bound, enabling broad geometry searches. A genetic algorithm (GA) guided by this metric searches over fixed-cardinality crystal arrangements to identify high-performing designs.

Applied to the SCI module, the GA converged within 50 generations and identified an optimized arrangement producing narrower FIM correlation peaks throughout the field of view than a heuristic design. GATE Monte Carlo simulations of a Derenzo phantom confirmed improved recovery of the 8 mm sphere group with clearer feature separation, validating the optimization framework.

Abstract

Whole gamma imaging (WGI) is a novel imaging technique that combines PET and Compton imaging by inserting a scatterer detector ring inside a PET detector ring. One of the suitable nuclides for WGI is ^{89}Zr. ^{89}Zr emits a 909 keV single gamma ray after undergoing positron emission or electron capture to form ^{89m}Y. Because these 909 keV gamma rays are emitted approximately four times more frequently than positrons, hybrid imaging of WGI combining both modalities is expected to improve image quality compared to conventional ^{89}Zr-PET which uses only annihilation gamma rays. In this study, we aimed at finalizing the design of a clinical whole-body WGI system. The hybrid imaging method was applied to Geant4-simulated data of a whole-body WGI system. We modeled a system employing HR-GAGG crystals as the scatterer and LGSO crystals as the absorber. Measurement of an ^{89}Zr-filled NEMA IEC body phantom placed at the center of the field of view was simulated. Images were reconstructed using the hybrid reconstruction method combining PET and Compton events and compared with PET images reconstructed by the list-mode OSEM algorithm using only PET events. We calculated the percent contrast ($Q_{H,j}$) and percent background variability (N_j) for each sphere size *j* (10-37 mm). The results showed that, for large spheres with diameters of 22 mm or more, hybrid imaging reduced N_j[if gte msEquation 12]><m:oMath><m:sSub><m:sSubPr><m:ctrlPr></m:ctrlPr></m:sSubPr><m:e><span lang=EN-US style='font-size:10.0pt;font-family:"Cambria Math",serif;mso-fareast-font-family: "ＭＳ 明朝";mso-fareast-theme-font:minor-fareast;mso-bidi-font-family:"Times New Roman"; mso-ansi-language:EN-US;mso-fareast-language:JA;mso-bidi-language:AR-SA'><m:r><m:rPr><m:scr m:val="roman"/><m:sty m:val="bi"/></m:rPr>N</m:r></m:e><m:sub><span lang=EN-US style='font-size:10.0pt;font-family:"Cambria Math",serif; mso-fareast-font-family:"ＭＳ 明朝";mso-fareast-theme-font:minor-fareast; mso-bidi-font-family:"Times New Roman";mso-ansi-language:EN-US;mso-fareast-language: JA;mso-bidi-language:AR-SA'><m:r><m:rPr><m:scr m:val="roman"/><m:sty m:val="bi"/></m:rPr>j</m:r></m:sub></m:sSub></m:oMath><![endif], but the maximum achievable $Q_{H,j}$ was lower than that of PET. In contrast, for small spheres with diameters of 17 mm or less, hybrid imaging demonstrated a specific advantage by suppressing noise amplification while accelerating contrast recovery in the early iterations. In conclusion, although the overall image quality improvement was limited in certain aspects, the

potential to enable novel applications such as multi-isotope imaging and positronium lifetime imaging using appropriate position emitters was suggested.

Abstract

Accurate positron emission tomography (PET) depends on calibration of detector alignment, gamma interaction positioning, and coincidence timing, which jointly define line-of-response (LOR) and time-of-flight (TOF) information. Conventional workflows calibrate these quantities in separate stages using dedicated acquisitions, hardware, or phantoms. This is particularly burdensome for light-sharing detectors, where these quantities are coupled through the detector response but are typically treated as separate calibration tasks. We introduce a differentiable in-system calibration framework that enables rapid scanner-level calibration by replacing staged workflows with a single coincidence-level optimization. A shared neural network predicts local interaction positions and timing corrections from single-event readouts, while learnable detector poses map predictions into scanner coordinates. Singles are processed independently, and coincidence information enters only via physical LOR and TOF construction. This prevents source-label access at the network input while enforcing scanner-level consistency. The framework was trained on 28M coincidences from 450 randomized 22Na point-source positions acquired on a semi-monolithic preclinical PET system. In hot-rod reconstructions, the proposed calibration achieved image quality on par with a conventional blueprint and fan-beam workflow, as assessed by peak signal-to-noise ratio, structural similarity, coefficient of variation, recovery coefficients, and peak-to-valley ratios. Differentiable in-system calibration therefore compresses labor-intensive staged workflows into a unified physics-constrained optimization completed in hours, reducing effort and mechanical constraints without sacrificing reconstruction performance.

A Compact Preclinical PET Scanner Achieving NEMA-Standard Sub-0.5 mm Spatial Resolution via Analytic FBP Reconstruction (#1867)

Chenxi Li[1], Haoqi Wen[1], Yuhao Jiang[1,2], Yucun Hou[1], Kexin Wang[1], Jianyong Jiang[1]

This work was supported in part by the NSFC (No. 12475336).

Abstract

PET is a cornerstone of preclinical imaging, where achieving ultra-high spatial resolution is paramount for the precise quantification of sub-regional metabolism. While commercial scanners typically yield 1.0–1.5 mm resolution, advanced research prototypes target sub-millimeter precision. This study introduces a compact preclinical PET scanner achieving NEMA-standard sub-0.5 mm spatial resolution via the analytic filtered back-projection (FBP) algorithm. To the best of our knowledge, this is the first reported system demonstrating such resolution through FBP. The dual-ring scanner features a 64 mm transaxial and 53.2 mm axial field of view, integrating 16 modules of 44 × 44 LYSO crystal arrays (0.497 × 0.497 × 5 mm^3 elements). These arrays are coupled to Hamamatsu Multi-Pixel Photon Counters (MPPCs, S14161-3050HS-08) and managed by a PETsys TOFPET2 ASIC system. System performance was characterized following NEMA NU 4-2008 protocols. The scanner demonstrated an overall energy resolution of 13.43% and an absolute sensitivity of 0.87% (350–650 keV). Peak true and noise equivalent count rates (NECR) were 7.61 kcps and 6.02 kcps, respectively, with a scatter fraction of 8.92%. FBP reconstruction of a point source demonstrated the system achieved average FWHM resolutions of 0.90 mm, 0.86 mm, and 0.69 mm in the radial, tangential, and axial directions, respectively, reaching a peak resolution of 0.48 mm. Imaging of a Micro-Derenzo phantom resolved 0.4 mm rods via iterative reconstruction. *In vivo* studies using ^{18}F-FDG and ^{18}F-Florbetazine delineated precise tracer distributions within sub-regional structures. While the 5-mm scintillator thickness involves a trade-off in sensitivity, the system establishes a benchmark for spatial fidelity in preclinical instrumentation. Future work will integrate thicker crystals with depth-of-interaction capabilities to enhance sensitivity without compromising spatial precision.

Development of a ring-type Quantum Entanglement PET Imaging System and Application of a Novel Image Reconstruction Algorithm to In-Vivo Imaging (#1680)

Koki Nakamura[1], Macoto Fujimoto[2], Pietro Caradonna[1], Mizuki Uenomachi[3], Laura Stephenson[4], Dan Watts[4], Kenji Shimazoe[1,2]

[1] The University of Tokyo, Department of Nuclear Engineering and Management, Graduate School of Engineering, Tokyo, Japan; [2] The University of Tokyo, Department of Bioengineering, Graduate School of Engineering, Tokyo, Japan; [3] Institute of Science Tokyo, Institute of Integrated Research, Tokyo, Japan; [4] University of York, York, UK

Abstract

Current positron emission tomography (PET) imaging is fundamentally limited by physical background noise, such as scatter and random coincidences, which significantly degrade image quality and quantitative accuracy. Quantum-entangled PET (QEPET) is a promising solution that utilizes the inherent orthogonal polarization correlation of annihilation photon pairs to physically reject noise. However, its practical application to in-vivo imaging has been a major challenge due to the severe reduction in usable event statistics caused by strict event selection. In this study, we developed a triple-ring PET scanner consisting of 24 Ce:GAGG modules (8×8 arrays of 2.5×2.5×9.0 mm³ pixels at 3.2 mm pitch; 1536 pixels in total) arranged in three axial rings with an inner radius of 36.7 mm, read out by SiPMs via dynamic time-over-threshold circuits, achieving an energy resolution of 9.5% at 511 keV and a coincidence timing resolution of 16.8 ns. By selecting events within a scattering-angle range of 70°–121° and an azimuthal-angle difference of 80°–100°, we obtained a modulation contrast ratio of 1.91, which clearly exceeds the classical limit of 1.63, confirming the entanglement of annihilation photon pairs. Furthermore, to overcome the limited counting statistics of conventional QEPET, we developed a novel reconstruction algorithm that seamlessly integrates the high-statistics structural information of standard PET into the iterative MLEM process. In phantom experiments, this approach improved the SBR to ~1.25× that of raw QEPET while preserving an SNR ~1.27× that of standard PET, achieving the highest CNR among the compared methods. Finally, we performed in-vivo QEPET imaging of a tumor-bearing mouse. The developed method effectively suppressed the granular noise characteristic of conventional QEPET while demonstrating highly localized tracer accumulation, thereby verifying its superiority over both standard PET and conventional QEPET.

SIMPLE-DIP: Positronium Lifetime Image Reconstruction Using Deep Image Prior (#2252)

Bangyan Huang, Jinyi Qi

University of California, Davis, Biomedical Engineering, Davis, USA

This work is supported by the National Institutes of Health, under Grant No. U01AG82845.

Abstract

Positronium lifetime tomography (PLT) is an emerging imaging modality for imaging positronium lifetime in vivo. Previously, we developed SIMPLE (Statistical IMage reconstruction of Positron Lifetime via time-wEighting), a reconstruction framework for estimating average positron lifetime images, and demonstrated high-resolution imaging on a phantom at clinical activity levels. However, the reconstruction problem remains highly ill-posed, particularly under low-count and high-random conditions. In this work, we propose SIMPLE-DIP, a deep image prior (DIP)-based reconstruction method that regularizes SIMPLE without requiring external training data. The proposed approach employs a single patient-specific U-Net that takes a prior anatomical image as input and jointly constrains both the activity and lifetime-weighted images during reconstruction. Computer simulations using a brain phantom show that SIMPLE-DIP effectively suppresses image noise while preserving lifetime contrast and improving lesion recovery, outperforming the compared SIMPLE formulations regularized by the quadratic penalty or independent DIPs. These results suggest that the proposed SIMPLE-DIP is a promising method for high-resolution positronium lifetime imaging.

AI-Based Predictive Dosimetry from PET for 177Lu-PSMA Radiopharmaceutical Therapy for Prostate Cancer (#2210)

Bowen Lei, Tzu-An Song, Fan Yang, Vibha Balaji, Joyita Dutta

University of Massachusetts Amherst, Biomedical Engineering, Amherst, USA

Abstract

Personalized 177Lu-PSMA-617 radiopharmaceutical therapy (RPT) for prostate cancer requires patient-specific dosimetry, but post-therapy SPECT imaging for dose computation is not universally performed. In contrast, pre-therapy PSMA PET is widely available and often mandatory for patient selection. PET-based predictive dosimetry therefore has the potential to enable personalized treatment planning before RPT administration. We developed a machine learning framework for organ-level predictive dosimetry from pre-therapy PET, where PET-derived organ features are used to predict kinetic parameters of post-therapy SPECT time-activity curves (TACs). Organ masks for the liver, spleen, and bilateral kidneys were used to extract PET features. Serial 177Lu-PSMA SPECT images at multiple post-injection time points provided reference organ activity values, from which mono-exponential fitting yielded organ TACs and time-integrated activities (TIAs). Absorbed dose was computed from TIAs using the MIRD formalism with organ-specific S values. Our deep learning model predicting kinetic parameters outperformed a comparable deep learning model predicting TIA directly, as well as three classical machine learning models predicting kinetic parameters. This workflow demonstrates the feasibility of forecasting organ absorbed dose from pre-therapy PET, supporting individualized therapeutic regimen planning.

Event-Resolved Parent-Progeny Discrimination Using CMOS Lensless Radiomicroscopy for ^{225}Ac Targeted Alpha Therapy (#2026)

Hyeyeun Chu[1,3], Jae Sung Lee[1,2]

[1] Seoul National University, Interdisciplinary Program in Bioengineering, College of Engineering, Seoul, South Korea; [2] Seoul National University, Department of Nuclear Medicine, Seoul, South Korea; [3] Seoul National Graduate School, Integrated Major in Innovative Medical Science, Seoul, South Korea

Abstract

Although targeted alpha therapy (TAT) using ^{225}Ac has demonstrated high therapeutic efficacy, clinical translation remains limited due to redistribution of daughter isotopes, leading to off-target dose. Therefore, discriminating localized emissions from redistributed emitting progeny is significant for small-scale dosimetry and radiopharmaceutical evaluation. Here, we propose a low-cost CMOS-based lensless radiomicroscopy system for direct / discrimination using cluster morphology. Event level features extracted from ^{210}Po and ^{90}Sr measurements

were used for classification applying both a physics-driven probability density function (PDF) approach and a data-driven multilayer perceptron (MLP). Both methods achieved > 98% accuracy with AUC > 0.99. Mixed-source experiments mimicking ^{225}Ac decay conditions demonstrated robust event-level discrimination. These results indicate that cluster morphology encodes sufficient physical information to monitor daughter isotope migration, enabling pathway toward quantifying parent and progeny distributions in radiopharmaceutical imaging.

Abstract
Actinium-225 (Ac-225) is a promising alpha-emitting radionuclide for targeted alpha therapy, and Compton cameras have emerged as a potential imaging solution for this radionuclide. We developed a physics-guided implicit neural representation (PG-INR) framework for Ac-225 Compton image reconstruction that does not require any ground truth data. Unlike conventional deep learning approaches, the proposed method incorporates physical laws directly into the training process by embedding physics-based loss terms, including maximum-likelihood estimation and Klein-Nishina differential cross section. This enables unsupervised learning solely guided by the measurement results. Furthermore, by representing the reconstructed image as a continuous implicit neural function, the framework achieves resolution enhancement beyond the native voxel grid. The proposed method was evaluated against a conventional ordered subsets expectation maximization (OSEM) algorithm using measured Compton imaging data from a mouse phantom and a Monte Carlo-simulated resolution phantom (from 1.0 to 2.5 mm). For the mouse phantom experiments, PG-INR achieved up to 18-fold faster reconstruction compared to OSEM at comparable resolution. For the resolution phantom simulation, PG-INR successfully resolved 1.0 mm diameter rods with up to 4.8 dB peak signal-to-noise ratio improvement and 0.25 structural similarity index measure

enhancement over OSEM. These results suggest that the PG-INR performs significantly better than standard OSEM for Ac-225 Compton imaging.

Attenuation Map Estimation from NAC Brain PET Images Using a 3D Patch-Based U-Net: A Multi-Tracer Study on the NeuroEXPLORER

(#1934)

Max Keppens, Georg Schramm, Hélène Goesseye, Koen Van Laere

KU Leuven, Department of Imaging and Pathology, Leuven, Belgium

Abstract

Attenuation correction in PET/CT imaging typically uses a CT-derived attenuation map (μ-map), prone to misalignment artifacts, CT-induced artifacts, and additional radiation dose. CT-free alternatives are therefore clinically attractive, and deep learning methods are a promising solution. As clinical PET centres increasingly adopt diverse tracer protocols beyond FDG, a single attenuation correction model that generalizes across tracers without retraining would further reduce deployment complexity. In this work, we investigate the feasibility of supervised μ-map estimation from non-attenuation-corrected (NAC) brain PET images using a 3D patch-based U-Net, trained and evaluated on patient data from the NeuroEXPLORER, a brain- dedicated PET/CT scanner. A dataset of 353 scans across 12 different tracers was used to study the effect of tracer composition on model generalizability. To our knowledge, this is the first study to systematically assess how training tracer composition affects cross-tracer generalization in deep learning-based CT- free attenuation correction, using a large multi-tracer cohort. The tuned U-Net outperformed Attention U-Net, HighResNet, and Swin UNETR under matched conditions. FDG-only training showed poor generalization to non-FDG tracers, with Normalized Root Mean Squared Error (NRMSE) on average 5× higher in the brain for non-FDG tracers than multi-tracer models across different dataset sizes. Notably, a model trained without any FDG data produced FDG μ-maps as well as a FDG-only model, suggesting the network learns anatomy-based priors that generalize across tracer distributions. Tracer diversity during training did not degrade FDG performance and improved generalization. Weighted resampling to correct FDG/non-FDG imbalance

worsened performance when the non-FDG patient pool was small. These results indicate that training set diversity, rather than size or tracer-specific data, is an important driver of generalization.

Abstract

Targeted alpha therapy is a very promising treatment modality for numerous types of cancer. Although PET presents an excellent resolution and signal-to-noise ratio, this modality is limited to radionuclides that emit positrons and cannot be used to image alpha radionuclides such as Ac-225 and Pb-212. Therefore, SPECT is the imaging modality of choice for these radionuclides, despite its poor signal-to-noise ratio and low quantitative accuracy due to the extremely limited sensitivity of this modality. We propose a new approach that enables imaging of alpha-emitting radionuclides in PET/CT scanners: time-of-flight cascade gamma-ray imaging. Our methodology exploits the coincidence detection of gamma-ray cascades emitted by ^{225}Ac or ^{212}Pb to perform tomography of non-positron emitters in PET/CT scanners. Our technique is evaluated with Ac-225 and Pb-212 phantoms at low concentrations of ~44kBq/mL and short scan sessions under 5-minutes in a commercial clinical PET/CT. We also present the first clinical image of a prostate cancer patient injected with 225Ac-PSMA-617 in a clinical PET/CT system. Lastly, we predict via simulations that next-generation long-axial field-of-view PET/CT scanners will achieve a sensitivity several orders of magnitude higher than SPECT with similar or better spatial resolution.

Abstract

Imaging of theranostic radionuclides that emit high-energy (MeV range) γ rays remains extremely challenging with conventional imaging systems. SPECT performance degrades at MeV energies due to scatter and collimator penetration, while PET is inherently restricted to positron-emitting radionuclides. Pair production tomography (PPT) offers a new approach enabled by the high-energy γ interactions with matter to detectable coincidence signals. When a photon with energy ≥ $2m_ec^2$ (=1.022 MeV) undergoes pair production, the positron generated from this pair production leads to annihilation with the medium electron and emission of two 511 keV photons, enabling PET imaging. In this study, we experimentally demonstrate PPT using the ^{212}Pb decay chain, exploiting 2.617 MeV γ rays from ^{208}Tl. Monte Carlo simulations indicate that, despite long photon transport distances, the spatial distributions of pair production and annihilation events remain localized at the millimeter scale. Phantom experiments were performed on both clinical time-of-flight (TOF) PET and preclinical non-TOF PET systems without hardware modification using clinically and preclinically relevant ^{212}Pb activity levels. Reconstructed PPT images successfully recovered the spatial distribution of activity, with improved contrast observed when TOF information was available. Corresponding SPECT measurements under identical conditions showed reduced visibility for smaller structures. Our results demonstrate the feasibility of PPT for imaging high-energy γ-emitting radionuclides and suggest a route to extend PET beyond conventional principles requiring positron emissions directly from radionuclides.

Abstract

X-ray based radiotherapy is indispensable in modern cancer treatment yet has challenges because it is an open-loop treatment, with limited ability to verify during treatment whether the delivered dose matches the treatment plan. To address this problem, we investigated the use of positrons which are generated in a patient body during X-ray radiotherapy through pair production interactions between matter and MV X-rays, and proposed a novel imaging modality termed pair-production tomography (P2T). This is possible because the X-ray energy used for radiotherapy is a few MeV, and pair production can occur when the photon energy is higher than 1.022 MeV, producing an electron–positron pair. Their simulation results showed opportunities to utilize pair-produced positrons to not only monitor the treatment but also differentiate materials with similar density but different effective atomic numbers, which remains challenging in conventional computed tomography. However, to our best knowledge, there has been no experimental evidence of pair-produced positron detection using a clinical linear accelerator (LINAC). Therefore, in this study, we performed experimental detection of pair-produced positrons using a LINAC. Experiments were conducted using a LINAC and a pair of radiation detectors composed of photomultiplier tubes and LYSO scintillator crystals. We successfully observed positrons generated in various phantoms via pair production. Furthermore, we quantitatively investigated sensitivity of P2T by adjusting the effective atomic number of phantoms, showing consistent results with the previous simulation results. These results provide an important step toward experimental validation of P2T.

Abstract

Terbium-149 (^{149}Tb) is a promising radionuclide for targeted α therapy that also emits positrons and prompt photons γ across a wide energy range, which makes it a candidate for ortho-positronium (oPs) lifetime imaging (oPsLI). We present the first demonstration of oPsLI with a therapeutic radionuclide and with γ energies below 511 keV on a commercial long-axial field-of-view PET/CT system. Using a three-lifetime-component Bayesian fitting model, we determined the oPs lifetime for the following three γ energy windows: 310 to 420 keV, 590 to 710 keV and above 720 keV. The medium- and high-energy windows yielded oPs lifetime values consistent with each other and with literature values, while the low-energy window produced systematically lower values. Voxel-wise oPsLI with small voxel size was successfully demonstrated using a single γ energy window. These results establish ^{149}Tb as a versatile probe for exploring γ energy window effects in oPsLI, with future potential for in vivo microdosimetry and chelator stability studies.

The first in vivo quantum entanglement imaging of a human subject (#3065)

Pawel Moskal, Deepak Kumar, Sushil Sharma, Ewa Ł. Stępień

Jagiellonian University, Institute of Physics, KRAKOW, Poland

We acknowledge support by National Science Center in Poland (2021/42/A/ST2/00423,2021/43/B/ST2/02150, 2022/47/I/NZ7/03112), Polish Ministry MNiSW (IAL/SP/596235/2023 and SPUB/SP/627733/2025), and European Union through ERC Advanced Grant POSITRONIUM no. 101199807.

Abstract

We present the first in-vivo imaging of the degree of quantum entanglement in a human subject. The reported investigations were conducted at the Cracow University Hospital in Poland using a 50 cm long, multi-photon J-PET

scanner capable of registering and imaging the degree of quantum entanglement of photons originating from electron-positron annihilations in the patient's body.
A 48-year-old male patient, administered 145 MBq of [68Ga]Ga-DOTA-TATE, was scanned for 20 minutes starting 90 minutes post-injection, following the completion of his routine diagnosis. Data were collected in a triggerless mode, enabling the simultaneous registration of annihilation photons and Compton scattered photons. Event selection was based on the position, time, and energy deposition of the annihilation and scattered photons.
The angular distributions between the scattering planes of annihilation photons in the patient's liver and spleen were determined. These distributions were used to extract the degree of quantum entanglement for these organs. The obtained degree of quantum entanglement is larger than expected for separable photons and lower than expected for maximally entangled photons.
These results demonstrate, for the first time, the feasibility of measuring the degree of quantum entanglement in annihilation photons originating from patients during positron emission tomography. This finding motivates the further development of detectors for the construction of PET systems capable of simultaneously capturing annihilation and Compton-scattered photons, and supports future studies aimed at uncovering medically useful information gained by imaging the degree of quantum entanglement.

Abstract
In addition to medical imaging applications, Positron Emission Tomography (PET) systems can be used to study fundamental physics. One pathway for positron-electron annihilation is the formation of ortho-positronium (oPs), an intermediate bound state that decays to photons after a short lifetime. The lifetime and decay kinematics of oPs can be used to probe material properties and test the Standard Model. Additional sources of charge conjugation-parity (CP) symmetry violation are required to explain the observed matter-antimatter imbalance in the Universe,

and CP violation can be constrained by measuring [if gte msEquation 12]><m:oMath><span style='font-size:12.0pt;line-height: 115%;font-family:"Cambria Math",serif;mso-fareast-font-family:Aptos; mso-fareast-theme-font:minor-latin;mso-bidi-font-family:"Times New Roman"; mso-ansi-language:EN-US;mso-fareast-language:EN-US;mso-bidi-language:AR-SA'><m:r>oPs</m:r><m:r>→3</m:r><m:r>γ</m:r></m:oMath><![endif][if gte vml 1]><v:shapetype id="_x0000_t75" coordsize="21600,21600" o:spt="75" o:preferrelative="t" path="m@4@5l@4@11@9@11@9@5xe" filled="f" stroked="f"> <v:stroke joinstyle="miter"/> <v:formulas> <v:f eqn="if lineDrawn pixelLineWidth 0"/> <v:f eqn="sum @0 1 0"/> <v:f eqn="sum 0 0 @1"/> <v:f eqn="prod @2 1 2"/> <v:f eqn="prod @3 21600 pixelWidth"/> <v:f eqn="prod @3 21600 pixelHeight"/> <v:f eqn="sum @0 0 1"/> <v:f eqn="prod @6 1 2"/> <v:f eqn="prod @7 21600 pixelWidth"/> <v:f eqn="sum @8 21600 0"/> <v:f eqn="prod @7 21600 pixelHeight"/> <v:f eqn="sum @10 21600 0"/> </v:formulas> <v:path o:extrusionok="f" gradientshapeok="t" o:connecttype="rect"/> <o:lock v:ext="edit" aspectratio="t"/></v:shapetype><v:shape id="_x0000_i1025" type="#_x0000_t75" style='width:50pt; height:16pt'> <v:imagedata src="file:////Users/msa54/Library/Group%20Containers/UBF8T346G9.Office/TemporaryItems/msohtmlclip/clip_image001.emz" o:title="" chromakey="white"/></v:shape><![endif] decays under the reversal of an applied magnetic field. A dedicated physics measurement platform was constructed from the architecture of the NeuroSphere brain PET insert for 7-T MRI, including a PET detector array, positronium target with lifetime trigger, and motorized gantry for control of the system orientation inside the 7-T environment. GATE simulations were used to inform the development of a custom data analysis pipeline for oPs event selection and multi-coincidence processing. Systematics were mitigated by combining runs with various target and detector positions (to average out artificial asymmetries caused by assembly or detector efficiency) and by applying a baseline correction from events in a kinematic region with vanishing analyzing power (to account for drift and more field- and material- related effects). Abstract

In nuclear medicine, positron emission tomography (PET) and single photon emission computed tomography (SPECT) exhibit high detection sensitivity by detecting γ-rays emitted from radiopharmaceuticals, but they are limited by poor spatial resolution. Conversely, Magnetic Resonance Imaging (MRI) achieves high spatial resolution by encoding positional information through Larmor precession induced by magnetic field gradients. To improve the spatial resolution in nuclear medicine, we propose a novel image reconstruction framework that integrates magnetic field–based spatial encoding, as utilized in MRI, with γ-ray detection as employed in PET and SPECT. By incorporating the effect of Larmor precession in perturbed angular correlation (PAC), we formulated a forward model that enables image reconstruction as an inverse problem. Numerical simulations demonstrated that our method can stabilize 7 by 7pixels imaging on a small-animal scale. Furthermore, condition number analysis revealed that the imaging process becomes increasingly stable as the neodymium magnets are scanned. However, since each magnetic field distribution requires several hours of measurement, future work will focus on designing more detailed field distributions to reduce measurement time while further enhancing spatial resolution.

Abstract

Task-based adaptive SPECT imaging has long been limited by the computational complexity associated with optimizing acquisition strategies over high-dimensional system configuration spaces. In this work, we present a computational framework for adaptive SPECT imaging based on direct optimization of imaging time distribution (ITD) over discretized detector poses. We have demonstrated the effectiveness of this scheme on a simulated robotic SPECT platform. The framework finds the best imaging strategy by finding an optimized imaging noise property based on the modified uniform Cramér–Rao bound (MUCRB). We further improve the computation efficiency using a non-uniform object-space pixelation (NUOP), which makes it possible to compute the optimum imaging geometry in real time. A StarGuide-inspired multi-head robotic SPECT was simulated and evaluated using a Hoffman brain phantom and hot- and cold-rod resolution-phantoms. Compared with conventional whole-view and uniform ITDs under identical total acquisition time, the optimized ITDs achieved substantially improved region-of-interest (ROI) image quality in all three phantoms and ROIs. These results demonstrate that the proposed framework enables efficient task-specific optimization of acquisition strategies for highly reconfigurable SPECT systems.

Cramér–Rao–Efficient Timing with Photon Counting: Theory and Proof-of-Concept Demonstration for Cherenkov TOF-PET (#1437)

Nicolaus Kratochwil[1], Seungeun Lee[2], Joshua W. Cates[2], Gerard Ariño-Estrada[1,3]

[1] University of California, Davis, Department of Biomedical Engineering, Davis, USA; [2] Lawrence Berkeley National Laboratory, Nuclear Science Division, Berkeley, USA; [3] Barcelona Institute of Science and Technology, Institut de Fisica d'Altes Energies, Barcelona, Spain

Abstract

Fast timing with Cherenkov luminescence has attracted significant interest in the medical imaging community over the last decade. While detector time resolutions of 100–200ps FWHM have been reported, we recently demonstrated that current timing estimators fail to fully exploit the prompt nature of Cherenkov emission. In particular, simulations of a small BGO crystal coupled to a state-of-the-art silicon photomultiplier (SiPM) yield a detector time resolution (standard deviation) of σ_t = 158ps when using only the first detected photon, whereas the Cramér–Rao lower bound (CRLB) predicts a ≈ 4.5-fold improvement to σ_t = 35ps for the same configuration.

To approach this limit, we apply a maximum-likelihood estimation (MLE) framework incorporating the full photon arrival time distribution. Using all detected photons, we obtain a harmonic average detector time resolution of σ_t = 35 ± 2ps, demonstrating statistically efficient timing estimation consistent with the CRLB. The MLE framework also enables event classification, identifying variations in Cherenkov photon yield and time biases from light transport and photon production. Simulations suggest a 2-fold timing improvement compared to state-of-the-art classifiers such as the signal rise time.

To validate this approach experimentally, we apply the method to a semi-monolithic BGO photon-counting detector (42 × 2 × 20 mm^3) measured in coincidence with a reference detector and read out by 16 SiPMs. Events with different Cherenkov photon yield can be identified, improving time resolution from 199ps (all events) to 165ps and 140ps FWHM for tighter log-likelihood selections. We observe a stronger improvement over the first timestamp for Cherenkov-rich events and shallow interaction depths.

These results demonstrate that photon-counting-based MLE can fully exploit the information content of Cherenkov emission, enabling a pathway toward CRLB-limited timing performance for improved TOF-PET imaging.

Sparse-to-Dense SiPM Readout Upsampling for Position Estimation in PET Detectors (#1583)

Fiammetta Pagano, Paula Muñoz Izquierdo, Antonio J. Gonzalez, Francis Loignon-Houle

CSIC-Universitat Politècnica de València, Institute for Instrumentation in Molecular Imaging (I3M), Valencia, Spain

Abstract

Signal readout strategies of positron emission tomography detectors have an inherent compromise between resolution and complexity, where finer photosensor sampling improves interaction localization but increases the number of readout channels and associated hardware demands. Channel-reduction methods are therefore central to detector design, though they typically can incur some loss in performance. Recent advances in deep learning offer a pathway to mitigate this compromise by recovering information lost through reduced readout. In this work, we propose a neural network–based sparse-to-dense mapping that reconstructs high-resolution (8×8) silicon photomultiplier signals from low-resolution (4×4) inputs. Data was acquired using a semi-monolithic scintillator array with pinhole collimation across both the monolithic and depth-of-interaction directions. An initial upsampling network is trained to transform 4×4 signals into 8×8 representations, which are then used as input to a second network for interaction position estimation. Performance is evaluated by comparing positioning accuracy across four configurations: native 8×8 readout, reduced 4×4 readout, upsampled 4×4-to-8×8 signals, and a conventional row–column summation (8+8) scheme. Results demonstrate that the proposed upsampling approach effectively reconstructs higher-resolution signal structure, helping to improve the monolithic and DOI resolution compared to both 4×4 and 8+8 readouts. This approach could therefore remove the need for additional hardware coming with conventional multiplexing techniques, while recovering the benefits of denser photosensor sampling.

Crosshair Light-Sharing Detectors with Diode-based Multiplexing for High-Resolution TOF-DOI PET (#2227)

Han Gyu Kang, Eiji Yoshida, Go Akamatsu, Taiga Yamaya

National Institutes for Quantum Science and Technology (QST), Advanced Nuclear Medicine Sciences, Chiba, Japan

This work was supported by Nakatani Foundation.

Abstract

Last year, we developed diode-based row-column multiplexing boards that can reduce the number of silicon photomultiplier (SiPM) channels by a factor of four without compromising the coincidence timing resolution (CTR). This technology is key to reducing the production costs of next-generation clinical whole-body time-of-flight positron emission tomography (TOF-PET) systems. However, we used one-to-one coupling detectors with a crystal pitch of 3.2 mm, which cannot provide depth-of-interaction (DOI) information. For brain PET applications, for example, DOI measurement capability with a finer crystal pitch is required. On the other hand, our group has developed crosshair light-sharing (CLS) detectors that can offer both TOF and DOI information with a crystal pitch half that of the SiPM pitch. In this work, therefore, we explored the performance of the CLS detectors with the multiplexing board in combination with a TOFPET2 ASIC module for high-resolution TOF-DOI brain PET imaging. The CLS detectors had a 14×14 array of fast-LGSO crystals (crystal pitch=1.6 mm, crystal thickness=15 mm) and an 8×8 SiPM array (Hamamatsu, S14161-3050HS). The multiplexed SiPM signals were digitized by the TOFPET2 ASIC module. We evaluated CTR at eight different detector positions of the multiplexing boards by shifting the CLS detector pairs and a ^{22}Na source. The diode multiplexing did not degrade the CTR and energy resolution compared to the case without multiplexing. The average CTR of 366±6 ps was obtained across the eight detector positions. In the future, we plan to further improve the CTR by using DOI information.

Abstract

Positron emission tomography can benefit from time-of-flight information between a coincident pair of PET detectors to enhance image quality. Improved coincidence time resolution (CTR) can not only improve image quality but also obviate the need for image reconstruction when the spatial uncertainty derived from CTR becomes sufficiently small to directly localize positron annihilation events within the patient body, potentially making PET systems more compact and flexible. The first reconstruction-free positron emission imaging termed direct positron emission imaging (dPEI), was demonstrated using detectors with 32 ps CTR; however, limitations such as low detection efficiency, lack of energy information due to the use of a pure Cherenkov radiator, and a small active area resulting from the single-channel detector system remain. To address these limitations and make dPEI more practical, we developed the first prototypes of a multi-anode bismuth germanate-integrated microchannel plate photomultiplier tube (MA-BGO-IMP). The MA-BGO-IMP is position-sensitive and has a two-dimensional 4 × 4 anode array with a 5.75 mm readout pitch. At the detector level, the transit time spread and quantum efficiency were measured to be ~40 ps full width at half maximum (FWHM) without circuit optimization and 31.4% at 380 nm without Fresnel reflection correction, respectively. A coincidence experiment was conducted using a ^{22}Na point source paired with a barium fluoride-integrated microchannel plate photomultiplier tube. The preliminary energy resolution and CTR were 26% FWHM at 511 keV and 56.2 ps FWHM, respectively. These results were obtained using signals from only one anode. At the conference, we will present more detailed characterization of these newly developed MA-BGO-IMPs with 511 keV-based coincidence results, including energy resolution, CTR, and spatial resolution using a pair of MA-BGO-IMPs.

This work is performed in the framework of the Crystal Clear Collaboration.

Abstract

Low-dose imaging and small-animal positron emission tomography (PET) require detectors with both high sensitivity and high spatial resolution. In this study, we investigate the performance of high-density scintillator matrices, such as BGO and LYSO:Ce, combined with multi-channel, low-noise, low-power, high-frequency (HF) readout electronics to enhance the Time-of-Flight (TOF) and Depth-of-Interaction (DOI) performance of pixelated detectors. High-frequency SiPM readout has demonstrated significant improvements in coincidence time resolution (CTR) by enabling the detection of ultrafast optical-photon production processes, such as Cherenkov emission in BGO and fast scintillation in LYSO:Ce. Two DOI-encoding detector designs are compared in this work: a double-sided readout and a single-sided readout employing a light guide to achieve DOI encoding through light sharing in laterally depolished crystal matrices. Experimental results demonstrate that they can achieve a timing resolution comparable to that of a standard pixelated matrix while also providing accurate DOI information. In particular, using 20 mm-long LYSO:Ce crystals, the light-sharing approach achieves a CTR of 133 ± 2 ps FWHM together with a DOI resolution of 2.2 ± 0.1 mm FWHM. Using a double-sided readout further improves the performance, reaching a CTR of 90 ± 2 ps FWHM and a DOI resolution of 1.9 ± 0.1 mm. Both DOI encoding methods provide similar DOI performance with LYSO:Ce matrices, while the advantage of collecting light from both ends of the scintillator becomes more evident with BGO crystals. In this case, the double-sided readout achieves a DOI resolution of 4.4 ± 0.1 mm, compared with 7.2 ± 0.2 mm obtained using the light-sharing approach. Future work will investigate the scalability of these detector concepts by extending the study from 16 to 64-channel prototypes and by comparing different readout electronics.

Deep Learning Limited Angle Artefact Correction for dual panel PET in Shearlet Domain (#2587)

Jens Maebe, Maya Abi Akl, Boris Vervenne, Stefaan Vandenberghe

Ghent University, Gent, Belgium

Abstract

Dual-flat-panel positron emission tomography (PET) systems offer strong advantages such as improved sensitivity but suffer from reconstruction artefacts due to missing projection data. We propose a deep learning model to correct these artefacts in the shearlet domain. The shearlet transform provides a multiscale, multidirectional analysis of the image, decomposing it into its shearlet coefficients, each corresponding to a subset of projections. A U-Net is used to correct for artefacts in these coefficients, but by only modifying coefficients corresponding to missing projection data, we can obtain an overall more robust algorithm. The model is trained and evaluated on data from a dual-panel PET system simulated in GATE, using real patient PET scans as the ground truth activity maps. The resulting artefact-corrected images showed good visual agreement with reference images from a system with full angular sampling. The standardized uptake value (SUV) mean of a hotspot also showed improvement (being closer to the reference value), but further investigation is required with regards to the consistency of quantitative accuracy of the model. Future work will also include an extension to 3D, to better leverage projection data along the axial dimension.

Abstract
Self-collimating (SC) SPECT employs a multi-layered, interspaced mosaic array detector structure to enable simultaneous gains in sensitivity and resolution. The complex configuration, however, demands a new set of imaging metrics and strategy to guide system design and optimization. In this work, we propose a Multi-Objective Bayesian Optimization (MOBO) framework based on four voxel-wise imaging metrics calculated from the projection probability density functions (PPDF) of the system: Angular Sampling Completeness Index (ASCI), average PPDF FWHM (full-width at half-maximum), Multiplex Index (MPXI), and sensitivity, to predict a design's performance and efficiently navigate the design space.
Through analytical simulations, we study a SC small animal SPECT that consists of a cylindrical tungsten high-resolution collimator ring surrounded by four concentric detector rings. In an initial test, we seek optimal design parameters for the aperture diameter, the number of apertures on the collimator ring, and crystal counts in two independent detector rings. The MOBO agent uses independent Gaussian process surrogates with log noisy expected hypervolume improvement to propose Pareto-improving configurations sequentially.
Results of MOBO search confirm that the four objectives genuinely conflict, which is desired, and provide recommended parameters balancing resolution, sensitivity, angular coverage, and multiplexing. Validation studies of the MOBO recommendations are underway.

Abstract

Cascade γ coincidence imaging can provide stronger geometric constraints than conventional single-photon imaging by exploiting the coincident detection of two cascade photons, but its reconstruction is challenging due to the complex system response and spatially non-uniform sensitivity. This work proposes a physics-prior-driven deep reconstruction framework for small-animal cascade γ coincidence imaging. A direct back-projection(DBP) reconstruction image was used as a physics-informed initialization, and a cascade sensitivity map was incorporated into a gated 3D ResUNet as a system-level spatial prior. Patch-based training was further adopted for sparse point-source reconstruction to reduce foreground-background imbalance. Monte Carlo simulations showed that, for a single-point source, the proposed method reduced the mean FWHM from 1.50 mm to 0.87 mm, increased the PSNR from 43.85 dB to 54.48 dB, and reduced the peak localization error from 0.25 mm to nearly 0 mm compared with DBP reconstruction. For the hotrod phantom, the foreground MAE decreased from 0.886 to 0.142, indicating improved recovery of extended active structures. The sensitivity map comparison further showed that different incorporation strategies lead to different trade-offs between foreground recovery and background suppression. These results demonstrate that the proposed framework provides a feasible route toward fast, sensitivity-aware, and physically informed reconstruction for cascade γ coincidence imaging.

Abstract

Bone metastases are common in advanced malignancies, and SPECT/CT provides complementary 3D radiotracer uptake and anatomy for screening and follow-up. Automatic whole-body lesion localization can reduce reading burden and improve consistency in patient-level assessment. However, it remains challenging because a detector needs to balance high-recall whole-body search, false-positive suppression, and fine-resolution local detail under memory and runtime constraints. To address this challenge, we propose a two-stage retrieval-augmented lesion detection framework: a 3D Swin Transformer-FPN-FCOS detector retrieves candidates from coarse-voxel-spacing whole-body SPECT/CT, and a candidate query retrieves fine-voxel-spacing local/context SPECT/CT evidence tokens for classification, box refinement, and rescoring. In validation, the base model achieves free-response receiver operating characteristic (FROC) scores of 0.511/0.471 for Mean-FROC/Low-FROC and reduces inference time from 14.9 to 3.6 s/patient; a final reranker raises Mean-FROC to 0.530 at 5.5 s/patient.

Abstract

Lung cancer remains a leading cause of cancer-related death, and distinguishing between the two major non-small cell lung cancer (NSCLC) subtypes, adenocarcinoma (ADC) and squamous cell carcinoma (SCC), is essential for treatment planning. To evaluate whether data augmentation strategies can improve subtype classification on computed tomography (CT) images with reduced annotation burden, we compared pseudo-color mapping, adaptive histogram equalization, pixel inversion, and rotation-based augmentation in combination with tumor-centric and lung-centric region extraction. Using the public NSCLC-Radiomics dataset, features were extracted with a pretrained ResNet-50 network and classified with support vector machine (SVM) and k-nearest neighbors (KNN) models, with all augmentation and feature selection performed within each cross-validation fold. Rotation consistently improved classification, with the best single model reaching 89.36% patient-level classification accuracy. Tumor-centric and lung-centric strategies showed complementary error patterns, and an ensemble of five complementary models achieved 100% patient-level classification accuracy on this cohort. The findings suggest that complementary augmentation pathways can diversify feature representations and improve classification stability in small-sample studies.

Abstract

Proton range verification (PRV) in proton therapy is an outstanding clinical need. Prompt-gammas (PG) emitted along the proton track constitute a strong signal to determine the Bragg Peak position. However, the high energy of PGs (1-7 MeV), the high particle flux and the presence of significant background radiation make prompt-gamma imaging (PGI) challenging.

We report on the development of pure Cherenkov pixelated detectors for PRV. The detector consisted of an 8×8 pixelated PbF2 crystal array coupled to an 8×8 S14161-3050HS-08 SiPM array from Hamamatsu, read out by a row-column signal processing board. Two analytical event reconstruction algorithms were evaluated: rise-to-the-power with k=2 (RTP2) and k=3 (RTP3).

The detector was exposed to both a sealed 228Th source and a 67.5 MeV proton beam at a current of 100 pA. Floodmaps were obtained using both RTP2 and RTP3 methods to resolve the 8×8 matrix of the crystal under laboratory source irradiation. Similar results were obtained under proton beam irradiation, showing the robustness of this detector concept.

In this contribution we demonstrate for the first time the ability of a pixelated pure Cherenkov detector to provide spatial resolution information in clinically relevant proton beam conditions. The prompt emission of Cherenkov light and exclusive sensitivity to highly energetic PGs offer a very high count rate capability, effective background rejection, and capacity to multiplex signals, enabling to use less channels and low power readout electronics. Future work will focus on quantitative floodmap quality metrics, detector modeling to optimize the detector geometry, and acquisition of additional data in the proton beam line at higher proton energies and beam currents.

Abstract

Accurate proton range verification (PRV) in proton therapy (PT) is an unmet clinical need and is essential to exploit the full potential of PT to maximize treatment effectiveness and minimize toxicity. We present a Monte Carlo (GATE 10) study of a Cherenkov-based prompt gamma imaging system combining an array of PbF2 crystal detectors with a MURA coded-aperture collimator for real-time PRV. The detector response was studied through detected Cherenkov photon distributions generated by prompt-gammas with energies ranging from 0.5 MeV to 7.0 MeV in steps of 0.5 MeV. A threshold of 15 detected Cherenkov photons was applied to reject low-energy background, which effectively suppressed 511 keV annihilation gammas and sub-MeV contributions while retaining the prompt gammas of interest. Image reconstruction was performed using the Maximum Likelihood Expectation Maximization algorithm, with the system matrix computed with 4.4 MeV point-like sources. The imaging performance was validated on isotropic gamma point sources in both 1D and 2D coded-mask configurations across a field of view of ~130 mm. A direct comparison between discrimination based on energy deposition (E > 1 MeV) and discrimination based on the number of detected Cherenkov photons (nckv ≥ 15) showed comparable performance, with position residuals consistent with zero within statistical uncertainties in both cases. For the proton beam measurements, background rejection was performed exclusively via the Cherenkov photon count threshold. Under realistic proton beam conditions, the distal fall-off position was reconstructed with a systematic residual below 1.5 mm and a statistical precision of less than 2 mm for beam intensities above 10^8 protons, corresponding to approximately 10 ms of irradiation at a standard proton current of 2 nA (1.25 × 10^10 protons/s). This work presents the concept and shows the feasibility of using Cherenkov-based coded-aperture imaging for PRV by means of a simulation framework.

This work has been sponsored by GE HeathCare.

Abstract

Respiratory phase mismatches between PET and CT commonly cause artifacts in PET/CT, especially at lung–liver and lung–spleen interfaces. Since CT captures a single respiratory phase while PET reflects an average over breathing, this misalignment leads to attenuation correction errors and inaccurate lesion quantification, particularly near the liver dome. We propose a deep learning framework that uses PET-based pseudo-CT to guide deformable CT-to-PET alignment. A retrospective dataset of 10 18F-FDG exams with respiratory phase mismatch (banana) artifacts, scanned on a Total-Body BGO-based PET/CT scanner, was used for evaluation. A previously trained 3D residual neural network was used to generate pseudo-CT images from non-attenuation corrected (NAC) PET images. The pseudo-CT images, inherently aligned with the PET data, were then used as a reference for deformable registration of the CT images. The original and registered CT images were used for attenuation correction and reconstruction of the PET data using a BSREM algorithm. Regions of interested were placed in dome of the liver to quantitatively measure the SUV changes in those regions affected by the artifacts. Compared to baseline PET/CT without correction, the proposed method effectively reduced or eliminated respiratory-induced PET/CT misalignment artifacts were significantly reduced or eliminated. Quantitatively, the method achieved improvements in liver SUVmean towards the expected values. By leveraging the native alignment between PET and the generated pseudo-CT, the method avoids direct multimodal registration and instead enables accurate deformable alignment of CT to PET space. This approach improves attenuation correction and quantitative accuracy, with potential to enhance diagnostic confidence in routine clinical PET/CT imaging

Evaluation of TOF-DOI Crystal Topologies for the HD-MetaPET MRI Insert (#2140)

Thore Meyer[1], Giulia Terragni[2], David Schug[1,3], Yannick Kuhl[1], Bjoern Weissler[1,3], Eike Gegenmantel[3], Oliver Muelhens[3], Harald Radermacher[1], Marco Pizzichemi[2,4], Etiennette Auffray[2], Volkmar Schulz[1,3]

[1] RWTH Aachen University, Chair of Imaging and Computer Vision, Aachen, Germany; [2] CERN, Geneva, Switzerland; [3] Hyperion Hybrid Imaging Systems GmbH, Aachen, Germany; [4] University of Milano-Bicocca, Milan, Italy

This work is sponsored by the BMFTR, contract numbers 13GW0609A, 13GW0609B, 13GW0621A and 13GW0621B. Part of this work was performed in the framework of Crystal Clear Collaboration.

Abstract

The HD-MetaPET project is developing a high-resolution positron emission tomography insert for simultaneous magnetic resonance imaging. The insert will consist of 120 Hyperion Visor Max detector tiles with an area of 56.5 x 56.5 mm^2, arranged in two semi-circles and coupled to LYSO:Ce crystal scintillators. A crucial optimisation parameter for the upcoming system performance is the crystal topology. This study evaluates Time-of-Flight and Depth-of-Interaction positioning performance across several crystal topologies: continuous slabs, pseudoslabs, and pixelated arrays with a light guide coupled to the face opposite the photosensitive detector. The study utilizes the Hyperion Visor Max and a custom development board, both featuring the TOFPET2 ASIC. Experimental measurements are performed using a ^{22}Na point source. The preliminary results with crystals of different materials show that pixelated arrays with light guides outperform continuous slabs. Specifically, pixelated designs achieved a Coincidence Time Resolution of ≈235 ps, compared to >400 ps for the slabs. The results indicate that the pixelated designs utilizing the light guide also demonstrated superior accuracy in the evaluation of the Depth-of-Interaction. The pixelated light-guide topology shows promising performance, circumventing the traditional compromise between spatial depth accuracy and timing resolution. Consequently, this configuration emerges as a good candidate for integration into the upcoming HD-MetaPET scanner. While these preliminary results are promising, the comprehensive evaluations utilizing final-scale crystals of the same material and the final scanner electronics will be presented at the conference.

Abstract

Tracer kinetic modeling using the two-tissue (2T) compartment model remains challenging in dynamic SPECT imaging, particularly under realistic noise conditions. In this study, we propose a noise-robust Bayesian parameter estimation method that incorporates physiological prior information for the 2T model in dynamic SPECT imaging. To validate the proposed method, we conducted both simulation study and dynamic ^{99m}Tc-4BOH clinical study. The proposed method was compared with the conventional nonlinear least-squares (NLS) method. In the simulation study, the proposed method yielded lower relative bias in the estimated kinetic parameters (K_1, k_2, k_3, and k_4) than the NLS method under both low and high noise conditions. In the clinical ^{99m}Tc-4BOH study, K_1 estimated using the proposed method demonstrated significantly stronger agreement and lower relative bias with respect to head-to-head ^{13}N-NH_3 PET myocardial blood flow (MBF), which was used as the reference standard, than the NLS method. In conclusion, the proposed method substantially improved the accuracy and precision of parameter estimation for the 2T model compared with the NLS method.

Abstract

We propose a kinetic-consistent conditional flow matching framework for dynamic *[11C* raclopride PET SRTM parametric imaging. Conventional indirect SRTM fitting is vulnerable to frame-wise count noise, causing unstable voxel-wise *R1* , *k2* , and *BPND* maps. Using 105 scans from 35 subjects, count-reduced datasets were generated at 50%, 25%, and 10% of the original counts. The model refines reduced-count indirect SRTM estimates toward full-count SRTM pseudo-reference maps using kinetic consistency, count/noise conditioning, and physiological constraints, reducing *BPND* deviation, high-percentile errors, and kinetic-parameter disagreement compared with indirect SRTM and denoising and regularization-based baselines

Abstract

Metal implants can degrade CT image quality and introduce artifacts that affect dose calculation in particle therapy. This study investigates attenuation images (μ-MLAA) reconstructed from time-of-flight PET data using maximum-likelihood reconstruction of attenuation and activity for metal artifact reduction. The linearity of a calibration curve relating CT number to relative electron density was first evaluated using a PMMA phantom with metal and tissue-equivalent inserts. Metal artifacts were then studied in a water phantom containing a Ti6Al4V total endoprosthesis (TEP) implant. μ-MLAA attenuation images reconstructed from PET list mode data and CT images reconstructed using iterative metal artifact reduction (iMAR) were evaluated using gamma index analysis (10%, 1 mm) relative to an artifact-free reference slice. The calibration curve remained linear in the presence of metal inserts ($R^2 > 0.999$). For the TEP phantom, μ-MLAA images achieved a higher gamma pass rate (96.3%) than iMAR CT (70.8%). Using the calibration curve, the relative electron density of the TEP shaft was estimated as $n_{e,rel} = 3.58 \pm 0.12$ corresponding to a 3.5% deviation from reported reference values. These results indicate the potential of μ-MLAA images for reducing metal artifacts and supporting implant characterization in radiotherapy imaging.

Abstract

Purpose: We are developing a Personalized Remote Radiation Tracking Portable Organ Dosimetry Device (PRRT PODD) for at-home monitoring of patients receiving radiopharmaceutical therapy (RPT). We report on an FPGA-based data acquisition system capable of wireless communication in support of this goal.
Methods: Our acquisition system supports16-radiation detectors and outputs an energy histogram for each using a time-over-threshold (ToT) energy measurement. The electronics consists of a custom analog board that converts each detector's analog signal into a digital ToT signal; an FPGA board for signal processing; and a microcontroller board that serves as the system controller. The microcontroller communicates with the FPGA via UART to retrieve energy histogram data, manages system configuration parameters, and provides Bluetooth Low Energy connectivity to a mobile Android app. The electronics fits within the PODD's base assembly and can operate on cell phone battery power. Each detector has a small thermistor for individual probe temperature monitoring and to characterize MPPC gain versus temperature. An Android app was developed to control data acquisition and wireless transfer of data to a remote workstation. The detector and electronics acqusition system was tested using Tc-99m, Na-22 and Lu-177 radioactive sources at clinically relevant counting rates.
Results: Sixteen channel operation of our FPGA-based data acquisition system has been validated using a variety of radionuclides. The output properties of the probes have been characterized versus temperature to enable post acquisition normalization of signals.
Conclusion and future work: A compact, wireless 16-channel gamma spectroscopy system for remote monitoring of Lu-177 RTP was designed and tested. Future work includes implementing real-time temperature compensation based on continuous temperature readings, ensuring stable operation without post-processing.

Energy-Shifting: an efficient approach for Monte Carlo Particle Therapy Dose Calculation (#3092)

Chi-Hieu Pham[1], Didier Benoit[1], Vincent Bourbonne[1,2], Ulrike Schick[1,2], Dimitris Visvikis[1], Julien Bert[1]

[1] University of Brest, LaTIM, INSERM-UMR1101, Brest, France; [2] Brest Hospital University, Radiotherapy Department, Brest, France

Abstract
While recent deep learning techniques for accelerating Monte Carlo (MC) radiotherapy dose calculation have shown promising results, most state-of-the-art methods rely on a denoising paradigm. This approach aims to predict a high-sampling (HS) reference dose map from a fast low-sampling (LS) input. However, information loss and stochastic noise in LS inputs often limit the accurate recovery of fine structural details and dose gradients, and may lead to hallucinations. To address these limitations, we propose a novel learning framework, Energy-Shifting, which reconstructs a time-intensive polyenergetic HS dose distribution from a GPU-accelerated monoenergetic dose map. Our results demonstrate that this method significantly outperforms conventional denoising approaches in accuracy.

Treatment Monitoring System for Proton Therapy Based on Beam Range Measurement (#1067)

SeHyun Jang[1], Jaeho Cho[1], Goeun Lee[1], Taehyeon Eom[1], Junyoung Lee[1], Jong Hwi Jeong[2], Sung Hun Kim[2], Sungkoo Cho[3], Kwanghyun Jo[3], Chan Hyeong Kim[1]

[1] Hanyang University, Nuclear Engineering, Seoul, South Korea; [2] National Cancer Center, Proton Therapy Center, Goyang, South Korea; [3] Samsung Medical Center, Department of Radiation Oncology, Seoul, South Korea

Abstract

In proton therapy, range uncertainties can result in insufficient dose delivery to the tumor or unintended dose delivery to organs at risk (OARs). To address this, several range verification methods have been investigated, and prompt gamma imaging is considered a promising method due to the strong correlation between the dose profile and prompt gamma distribution at the distal dose fall-off location. Based on prompt gamma imaging, a treatment monitoring system was developed to measure the in vivo beam range and detect range shifts during the treatment. The developed system consists of a 72-slit parallel collimator, 144 CsI(Tl) scintillation detectors, a dedicated field-programmable gate array (FPGA)-based data acquisition (DAQ) system, and a dedicated program with a graphical user interface (GUI). The DAQ system calculates pulse height and timing of each signal from 144 detectors. The dedicated program reconstructs 1D prompt gamma distribution using pulse data and determines the beam range of each spot using a dedicated range estimation algorithm [1]. The system's performance was evaluated using a clinical proton beam prescribed to deliver 0.5 Gy to a spherical clinical target volume (CTV) with 50 mm diameter in a homogeneous PMMA phantom. To evaluate range shift detection performance, range shifts were induced at both the global range shift (1–10 mm) and local range shift (5 and 10 mm) conditions. At the same time, the computation time for range deviation analysis was evaluated. The system detected global range shifts with an accuracy of 1 mm and identified the presence and location of local range shifts exceeding 5 mm. Furthermore, the time required for range deviation analysis per layer was found much shorter than energy layer switching time. These results demonstrate the system can verify the in vivo beam range during treatment in clinical practice.

Abstract

Minimally-invasive radio-guided surgery requires simultaneous functional nuclear guidance and anatomical visualization to enable precise intraoperative localization of radiolabeled targets [1]. We propose a dual-modality imaging drop-in capsule designed for deployment through a standard 15-mm laparoscopic trocar. It consists of a 2-mm thick semiconductor detector with a sub-millimeter pixel pitch [2,3], a custom lofthole collimator embedded within a 3D-printed tungsten capsule, and two miniaturized stereoscopic micro-cameras.

Preliminary results show: real-time 3D depth maps validated against an ultrasonic distance sensor; a seamless 360° panoramic view stitched from sequential frames using cylindrical warping and multi-band Laplacian blending [4,5]; spectral localization of multiple isotopes ^{57}Co and ^{241}Am within a scattering biological medium; and a preliminary 2D co-registration overlaying the functional dataset onto the anatomical scene. We will present the system design and components, and discuss the steps towards a fully integrated prototype for laparoscopic radio-guided surgery.

Abstract

Lutetium-177 (^{177}Lu) is one of the most representative radionuclides in integrated nuclear medicine theranostics. To image ^{177}Lu, we have developed a full-ring, high-sensitivity cascade gamma photon coincidence imaging system. This work presents the system construction and preliminary performance evaluation.

The detector ring consists of 40 continuous $LaBr_3$ crystal modules arranged in 10 radial × 4 axial configuration (each 50 × 50 × 6 mm³). The inner diameter of the ring is 110 mm, with axial module spacing of 60 mm. Each crystal is coupled to four MPPC arrays and read out via PETsys FEM256 electronics, with three FEB/D boards and one DAQ for data acquisition. Both the ASICs and MPPCs are cooled by a water-cooling system, maintaining water at 8 °C and ASIC temperature below 20 °C.

The collimator assembly comprises 10 tungsten plates (26 × 128 × 8 mm³), each covering four axial detector modules. Plates are arranged alternately with pinholes and slits (1 mm), placed at a vertical distance of 36.5 mm from the ring center, creating an imaging field of Φ30 × 30 mm. The prototype hardware has been fully assembled and is capable of normal data acquisition.

Simulation results indicate a coincidence sensitivity of 2.97 × 10^{-5} at the central field of view, spatial resolution of ~1.7 mm, and hot cylindrical object resolution up to 1.2 mm. Preliminary experimental tests have validated the feasibility of the system. Ongoing optimization includes crystal position calibration, energy resolution improvement, and collimator geometry alignment. The full system performance evaluation is expected to be completed before the upcoming conference.

Abstract

In matter, a positron annihilates with an electron into two photons through several mechanisms, including direct annihilation and the formation of positronium, a metastable bound state that exists as either para-positronium or ortho-positronium. Each channel has a characteristic lifetime, allowing their contributions to be distinguished in time. The two photons are predicted to be entangled in their polarizations [1], and recent measurements indicate that the degree of entanglement depends on the annihilation channel [2]. In particular, the ortho-positronium decay is sensitive to the local concentration of molecular oxygen, and can serve as a probe of tissue hypoxia in PET imaging [3]. The Jagiellonian Positron Emission Tomograph is a scanner built from plastic scintillators, in which 511 keV photons interact predominantly through Compton scattering [4]. The Compton scattering plane of each photon is correlated with its polarization. We measure annihilations of positrons emitted by a sodium-22 source embedded in porous polymer. Sodium-22 emits a positron accompanied by a 1274 keV prompt photon, which provides a time reference for the positron lifetime. The polarization correlation distribution of the annihilation photon pairs is consistent with quantum entanglement, between the limits for maximally entangled and classically separable states [2]. Selecting events by positron lifetime reveals distinct polarization correlation distributions for different annihilation channels. A detailed comparison will be presented at the conference. These results motivate quantum-informed PET imaging, with tissue hypoxia as a clinical biomarker.

Abstract

This research presents the development and first in-vivo demonstration of Positronium Ratio Imaging, a novel functional imaging technique that uses the three-photon to two-photon decay ratio of positronium. While conventional Positron Emission Tomography primarily maps radiopharmaceutical distribution, Positronium Ratio Imaging provides insights into the tissue microenvironment by exploiting the sensitivity of ortho-positronium to local oxygen levels and morphology. We characterized the system's geometric stability using a four-rod phantom with varying dimensions and evaluated the results against Monte Carlo simulations using the Geant4 toolkit. The phantom study identified a size-dependent uncertainty baseline of approximately twenty percent, primarily arising from detector sensitivity and geometric factors. Furthermore, we achieved the first in-vivo ratio imaging using a tumor-bearing mouse model administered with fluorine-18 fluorodeoxyglucose. Quantitative analysis revealed that the three-photon to two-photon ratio in brown adipose tissue was approximately two and a half times higher than in the heart and bladder. This significant contrast is consistent with theoretical trends derived from tissue-specific positronium lifetimes and far exceeds the established hardware-induced uncertainty. These findings validate the feasibility of using standard positron emitters for functional three-photon imaging without the need for specialized prompt-gamma emitters. Future work will focus on refining quantitative calculation methods, evaluating signal-to-noise ratios, and implementing hardware-specific calibrations to enhance absolute quantification. This technology lays a foundation for clinical applications such as the non-invasive visualization of tumor hypoxia and metabolic characterization of the tissue microenvironment, offering a breakthrough in functional molecular imaging.

Abstract

We present quantitative 4D PET imaging of photosynthate carbon transport and rhizosphere exudation in intact Phaseolus vulgaris plant–soil systems using the R-PET (Rhizo-PET) scanner with the ^{11}C radiotracer ($t_1/_2$ = 20.3 min). Across N = 6 plants, time–activity curves (TACs) extracted from 225 cross-pattern ROIs per dataset—spanning 3 roots × 3 axial depths × ±3 mm radial extent—reveal a reproducible source-to-sink carbon allocation hierarchy: upper root zones receive ≈50% of total plant carbon, while root 2 (primary taproot) dominates at 20.8 ± 6.3%. Time-to-peak (TTP) increases from 31.5±4.4 min (upper) to 48.0±13.1 min (lower root 2), corresponding to a phloem transport velocity of ≈2.4 mm min^{-1}. Rhizosphere carbon exudation follows an exponential decay AUC(r) = A e^{-kr} with k = 0.10–0.20 mm^{-1}, placing the active deposition zone within 4–14 mm of the root surface—the first spatially resolved 3D+t measurement of this process in intact soil.

Comparative Evaluation of Respiratory Motion Correction Methods for Upright Walk-Through PET Using XCAT Simulations (#1444)

Rabia Aziz[1], Thibault D'Hulster[1], Jens Maebe[1], Christian Vanhove[1], Sun Tao[2], Stefaan Vandenberghe[1]

Abstract

Walk-through positron emission tomography (WT-PET) is an emerging upright imaging geometry based on two vertically opposing flat detector panels. Although this design may improve patient comfort and acquisition efficiency, respiratory motion remains a major source of image degradation. This study evaluates respiratory motion correction strategies for WT-PET using XCAT anthropomorphic simulations. A 30s acquisition was simulated in a WT-PET geometry and reconstructed using an in-house MLEM-based algorithm. Data-driven amplitude- and phase-based respiratory gating were followed by non-rigid motion correction using Advanced Normalization Tools (ANTs) and Fast Algorithms for Motion Correction (FALCON). Overlapping-frame reconstruction using 0.9375s windows shifted every 0.3125s was also evaluated to assess the effect of temporal smoothing. Performance was quantified against a motion-free reference using normalized root mean square error (NRMSE), diaphragm edge width, and line profile analysis. ANTs phase-based 4-gate correction achieved the best performance, reducing NRMSE from 64% to 6% and restoring the diaphragm edge width to the motion-free reference level (25.10 mm vs. 25.79 mm). FALCON phase-based 4-gate correction reduced NRMSE to 12% but showed limited recovery of diaphragm sharpness, with an edge width of 28.40 mm compared with 28.62 mm for no motion correction. Overlapping-frame ANTs correction reduced NRMSE to 15% and yielded an intermediate edge width of 27.13 mm, although line profiles indicated residual local displacement and smoothing. These findings show that data-driven respiratory gating combined with deformable registration can substantially improve image quality in upright WT-PET.

Abstract
We investigated whether a positron emission tomography-derived latent biomarker can serve as a compact prognostic signal after longitudinal modeling. The study used 3,458 scans from 1,624 participants in the Alzheimer's Disease Neuroimaging Initiative. A Bayesian mixed-effects model was fitted to the biomarker trajectory and evaluated in two practical settings: forecasting future visits for previously observed subjects and estimating short-term dementia risk from predicted biomarker values. For subjects already observed during training, future visits were predicted with a mean root mean squared error of 0.298 and a mean absolute error of 0.250. For entirely new subjects, a change-from-baseline formulation reduced prediction error to a mean root mean squared error of 0.217 and a mean absolute error of 0.171 after an initial scan. A training-only logistic calibration applied to held-out predictions reached an area under the receiver operating characteristic curve of 0.826 for future dementia risk estimation. These results suggest that the latent biomarker can move beyond representation learning and support short-term longitudinal forecasting and clinically interpretable risk stratification.

Abstract

Patient motion remains a common challenge in dynamic cardiac positron emission tomography (PET), as it degrades image quality and complicates reliable evaluation of motion correction methods. Realistic motion simulation requires motion models that capture the variability observed in clinical data, but this remains difficult when simulations rely on only a limited set of motion patterns. In this work, we propose a data driven framework for motion model selection and simulation in dynamic cardiac PET. We characterize motion trajectories using physically interpretable features and analyze them using clustering and trajectory similarity based on dynamic time warping to identify a compact set of representative motion models. These models are integrated with patient-specific motion scaling for frame-wise simulation of motion-corrupted PET data. The proposed framework produces stable normalized error levels across 1308 patient–model evaluations while using only a small number of representative motion models. The results suggest that the selected models effectively capture dominant motion behaviors observed in the dataset and enable realistic PET motion simulation.

[1] ShanghaiTech University, School of Information Science and Technology, Shanghai, China; [2] Shanghai United Imaging Healthcare Co., LTD, Molecular Imaging Business Unit, Shanghai, China

Abstract

Deep learning-based attenuation correction (DL-AC) offers potential advantages over conventional CT-based attenuation correction (CT-AC) in PET imaging, including avoidance of additional radiation exposure and reduced susceptibility to PET–CT misalignment. However, in DL-AC application scenarios, when CT-derived attenuation maps (CT-μ) are unavailable as reference images, quality control (QC) of deep learning-derived attenuation maps (DL-μ) often relies on manual inspection. To address this limitation, we propose a patch-level 3D convolutional neural network (3D CNN) framework for automated anomaly detection and localization in DL-μ without requiring CT during inference. During training, CT-μ was used to assist patch-level annotation of DL-μ, and artifact-free CT-μ patches without observer-identified abnormalities were incorporated as normal samples to help the model learn normal attenuation patterns. During inference, only DL-μ was used, and sliding-window prediction was used to aggregate patch-level anomaly probabilities into a voxel-wise anomaly probability map. On the validation set (51 cases), the framework yielded patch-level performance with an AUC of 0.9984, an F1-score of 0.9802, a sensitivity of 97.06%, and a specificity of 98.86%. These results suggest that the proposed framework can provide spatial cues for DL-μ, potentially supporting efficient evaluation and reducing reliance on manual QC inspection.

Characterizing Noise in Clinical Nuclear Medicine Modalities via Quantum-Inspired Framework (#2977)

Amirreza Hashemi, Shadi Abdar Esfahani, Pamela Silva, Anthony Sinagra, Pedram Heidari, Hamid Sabet

Harvard Medical School/Massachusetts General Hospital, Department of Radiology, Boston, USA

This work was supported in part by NIH grant R01EB034785.

Abstract
Quantum-inspired denoising is employed for clinical PET/CT, PET/MR, and SPECT imaging by treating images analogous to disordered materials and analyzing the eigenfunctions of an associated Hamiltonian. Quantum localization is quantified by the participation ratio, enabling filtering of non-localized, high-participation modes that dominate the mid-frequency range and are associated with diffusive noise. By suppressing these modes and reconstructing from the remaining localized modes, noise is reduced without training data or manual regularization. The framework is applied to 46 multi-vendor, multi-tracer patient datasets from Massachusetts General Brigham to characterize scanner-dependent noise structure and its impact on image appearance. Across the cohort, quantum-inspired filtering yields consistent decreases in blind image quality scores (PIQE and BRISQUE) together with increases in entropy and Laplacian variance, indicating lower perceived noise and enhanced structural detail in the denoised clinical images.

University of California at Davis, Biomedical Engineering, Davis, USA

This work was supported by the NIH R01 EB031961.

Abstract

Spatial resolution and sensitivity are the two most critical characteristics of a positron emission tomography (PET) scanner, as they determine the accuracy and precision of reconstructed images. Achieving uniform ultra-high spatial resolution across the field of view (FOV) while maintaining **sufficient** sensitivity requires PET detectors **capable of resolving** ultra-fine, high-aspect-ratio crystals **and extracting** precise depth-of-interaction (DOI) information to mitigate parallax errors. In this study, we developed and evaluated two dual-ended readout detectors for small-animal brain PET applications. Each detector comprised a 36 × 36 array of lutetium yttrium oxyorthosilicate (LYSO) or gadolinium aluminum gallium garnet (GAGG) coupled to two linearly-graded silicon photomultipliers (LG-SiPMs). The crystal element size of the two crystal arrays was 0.20 × 0.20 × 9 mm³, while the pitch of the two crystal arrays was 0.25 mm. Despite the crystal element aspect ratio reaching 45:1, most crystal elements in both detectors were resolved, yielding average energy resolutions of 37.3 ± 5.6% and 31.7 ± 5.7%, respectively, for the LYSO and GAGG arrays, resepectively. The mean coincidence timing resolutions (CTRs) of the central 32 × 32 crystal elements, measured using a 200–1000 keV energy window to select events, were 1025 ± 40 ps (LYSO array) and 1205 ± 62 ps (GAGG array). Additionally, the average DOI resolutions across crystal elements were 1.48 ± 0.10 mm and 1.47 ± 0.10 mm, respectively, for the LYSO and GAGG arrays, respectively.

Abstract

High-repetition-rate (HRR) operation is a key limitation in laser-driven particle and photon sources, requiring diagnostics compatible with repetition rates of order 1 Hz or higher. We investigate standard industrial CMOS imaging sensors as soft X-ray detectors, analysing their single-photon response in the 5.5--12.6 keV range. The response is linear, and the sensors are calibrated in terms of generated electron--hole carriers versus incident photon energy. X-ray interactions in pixel sensors produce single-pixel (SPE) and multi-pixel events (MPE), which are analysed independently; removing MPEs significantly improves spectral resolution. This work is a first step toward the systematic study of commercial CMOS sensors under exposure to high-energy particles and photons, including response, radiation tolerance and dynamic range. Their compact size, low cost, and intrinsic compatibility with high-repetition-rate operation make them suitable for laser-plasma, nuclear and particle physics, and biomedical applications.

This work is supported by the National Natural Science Foundation of China (Nos. 62371314 and 12275182), the National Key R&D Program of China (No. 2023YFC2414800), Guangdong Basic and Applied Basic Research Foundation (Nos. 2024A1515012154), the Guangdong Provincial Project (Grant No. 2023TQ07A233), the Major Program of Shenzhen Bay Laboratory (No. C1012530005) and the Shenzhen Bay Laboratory Proof-of Concept Grants (No. C1022430005).

Abstract

To address spatial resolution and sensitivity limitations in whole-body PET for small-organ imaging, such as heart, breast and prostate, this study developed an asymmetric dual-ended readout for TOF-DOI PET detectors.

The asymmetric readout design utilizes a 4×4 SiPM array (6×6 mm² pixels) with individual channel readout at the front end, for good timing performance . At the back end, an 8×8 SiPM array (3×3 mm² pixels) is read out using a diode-based row-column summing multiplexing circuit to facilitate event position decoding while reducing the number of readout channels. Specifically, the multiplexing scheme reduces the back end channels from 64 to 16, lowering the total channels per detector from 80 to 32. LYSO arrays with three crystal dimensions were evaluated: an 8×8 array (3.10×3.10×20 mm³ crystals), a 13×13 array (1.88×1.88×20 mm³ crystals), and a 16×16 array (1.50×1.50×20 mm³ crystals).

Detector performance was evaluated in an array-to-array coincidence setup, with two identical detector modules placed face-to-face. Flood images show all crystals in the three evaluated arrays can be clearly resolved under both non-multiplexed and multiplexed readout conditions. The average energy resolutions for the 8×8, 13×13, and 16×16 arrays are 12.49%, 11.71%, and 10.92%, respectively, which are comparable to those obtained with non-multiplexed readout . A preliminary evaluation of CTR for the 8×8 array yields 327 ps (non-multiplexed) and 365 ps (multiplexed), indicating limited timing degradation due to multiplexing.

The proposed asymmetric multiplexed readout design maintains acceptable spatial, energy, and timing resolution while substantially reducing electronic complexity . This configuration is suitable for developing cost-effective, high-performance organ-specific PET scanners . Future work will focus on optimizing the MPPC operating overvoltage and PETsys threshold settings, as well as implementing an interleaved multiplexing circuit to improve CTR performance.

Abstract

Time-of-flight (TOF) and depth-of-interaction (DOI) information improve the spatial resolution and signal-to-noise ratio of PET imaging, but typically requires numerous readout channels, increasing system complexity and cost. In this work, we developed a TOF-DOI PET detector using a novel dual-ended interleaved multiplexing (DiMux) readout. The detector consists of an 8×8 LYSO crystal array with polished surfaces, where each crystal measures 3.1 × 3.1 × 20 mm^3 with a 3.2 mm crystal pixel pitch, and is optically isolated using $BaSO_4$ reflectors. Both ends are one-to-one coupled to 8×8 SiPM arrays and read out by two complementary interleaved multiplexing circuits, which use Schottky barrier diode-based charge division. In this approach, each crystal is encoded as a row signal on one end and a column signal on the opposite end, with multiplexed signals digitized by PETsys TOFPET2 ASICs. This dual-ended, complementary design enables accurate position decoding using a conventional center-of-gravity (CoG) method, eliminating the need for deep learning-based decoding.

Flood images with clearly resolved crystals are generated from the summed signals of both ends. The detector achieves a average DOI resolution of 2.97 mm and a coincidence time resolution (CTR) of 257 ps, which further improves to 234 ps after excluding inter-crystal scattering (ICS) events. Compared with a non-multiplexed dual-ended reference detector, the DiMux scheme reduces the number of readout channels by a factor of four while maintaining comparable TOF and DOI performance.

These results demonstrate that the DiMux readout provides a high performance, low complexity, and scalable solution for clinical PET imaging systems.

Design of a Single-Ended Readout DOI PET Detector with BGO and Deep Learning (#1952)

Sungwook Hong, Jin Ho Jung, Jiwoong Jung, Yong Choi

Sogang University, Department of Electronic Engineering, Intelligent Signal Processing System (ISPS) Laboratory, Seoul, South Korea

This research was supported by the Korea Medical Device Development Foundation Grant funded by the Ministry of Science and ICT, the Ministry of Trade, Industry and Resources, the Ministry of Health & Welfare, the Ministry of Food and Drug Safety (no. 2410019162, no. RS-2026-25540876) and by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (no. RS-2023-00280177, no. RS-2025-21682968) of the Republic of Korea.

Abstract
The purpose of this study was to design a single-ended readout PET detector with BGO providing DOI, to investigate the effects of lateral surface treatments and inter-crystal coupling conditions on detector performance, and to improve the performance using deep learning. A detector consisting of an 8 × 8 array of 3 mm × 3 mm × 20 mm BGO, each one-to-one coupled with a SiPM, was modeled using DETECT2000. Photon distributions were estimated for four detector configurations: polished + air (PA), polished + glue (PG), unpolished + air (UA), and unpolished + glue (UG). The x-, y-, and z-positions were analytically estimated using photon distribution information. To improve positioning accuracy, a deep learning model combining CNN and MLP was implemented. The CNN extracted features from photon distributions, and the MLP estimated the fine position using CNN-derived features concatenated with analytically calculated positions. The difference between the ground-truth and the estimated positions was evaluated using the mean absolute error (MAE). The accuracy of DOI estimation was assessed by evaluating the DOI identification accuracy in 20 mm long BGO divided into three equal segments. For x- and y-position estimations, the MAE values showed minimal variations (< 0.1 mm) across the four detector configurations, regardless of the estimation methods. For DOI estimation, the UA and UG achieved lower MAE (3.8 and 3.6 mm) and higher DOI identification accuracies (63% and 66%) than the other detector configurations. By applying deep learning, the MAE values for UA and UG were reduced to approximately 1 mm, and the DOI accuracies increased to 92% and 91%, respectively. These results indicate that three-level DOI identification can be achieved using photon distribution information obtained from a simple single-ended readout detector. In particular, the UA provided superior DOI estimation performance, and the incorporation of deep learning further enhanced DOI positioning accuracy.

A pulse-train model for X-ray photon-counting scintillation detectors with pile-up (#2023)

Lukas Schröder, Dennis R. Schaart

Delft Univeristy of Technology, Radiation Science & Technology, Delft, Netherlands

Abstract

To investigate potential applications of indirect photon-counting detectors, we developed a model to simulate pulse trains with pile-up for a combination of scintillator and silicon photomultiplier (SiPM). We generated pulse trains for various input rates, and the output count rate (OCR) and the spectral degradation factor (SDF) were analyzed. This was performed for two scintillators and counting algorithms, various cut-off frequencies of the applied low-pass filter, event energy thresholds, and a mono- and a polychromatic source. The results were compared to experiments. For the OCR, the model and measurements produced very similar results for all investigated parameter combinations. While the SDF values of the simulations tended to show some differences compared to the measurements, the general trend was similar.

Abstract

This work investigates a collimator-less scintillator-based detector that uses penumbra maps to reconstruct the spatial origin of radioisotopes without photon losses from collimation, motivated by the need for in-vivo dosimetry monitoring during targeted radionuclide therapy (TRT) and the limitations for its broader clinical adoption. Monte Carlo simulations were performed in GATE to evaluate the method's viability, using a 218 keV mono-energetic point-like source to replicate the first gamma emission on Ac-225's decay scheme. Given its favorable photoelectric fraction for this energy, BGO was chosen as the detector's material on the simulations. Geometrical parameters such as crystal dimensions, inter-crystal spacing, and array layout were systematically varied. Results show that inter-crystal spacing significantly shapes the photon distribution pattern, the larger 0.4mm value produced a distinct visual artifact. Depth profiles vary with source position in a predictable manner and provide information regarding the radiation's penetration depth. The implemented dual-layer checkerboard geometry demonstrated complementary detection behavior between layers, improving spatial discrimination over single-layer designs. These findings support the feasibility of collimator-less gamma imaging and show that geometric optimization shapes the detector's spatial response.

A covariance-based framework for quantifying circuit and intrinsic CTR limits in TOF-PET detectors (#2237)

Hyeongseok Shim[1,2], Guen Bae Ko[2]

[1] Korea Advanced Institute of Science and Technology, Department of Nuclear and Quantum Engineering, Daejeon, South Korea; [2] Korea Advanced Institute of Science and Technology, Mechanical Engineering Research Institute, Daejeon, South Korea

This work was supported by the National Research Foundation of Korea(NRF) grant funded by the Korea government(MSIT) (RS-2026-25490510). The authors gratefully acknowledge Broadcom Inc. for providing the NUV-DJ SiPM that enabled this characterization.

Abstract

CTR in PET detectors is a quadrature combination of scintillator photon statistics, intrinsic detector physics, and front-end circuit electronics, but conventional measurement reports only the combined FWHM, leaving the relative contributions indeterminate. This hinders rational optimization between circuit-side and detector-side improvements. We introduce a covariance-based framework that decomposes the CTR noise budget from a single coincidence measurement by simultaneously extracting timestamps from two independent readouts—the timing chain and the energy chain. The covariance $\mathrm{Cov}(\Delta T_T, \Delta T_E)$ isolates the common-mode intrinsic contribution, while variance differences identify chain-specific circuit noise in closed form, requiring no calibration beyond standard CTR acquisition. Applied to a 4 condition of LSO and GAGG:Ce (3×3×20 mm³) with Broadcom NUV-MT and NUV-DJ SiPMs, the framework extracts a circuit noise floor σ_{nT} = 11.2–18.5 ps per detector across all conditions, supporting its interpretation as a detector-independent electronics floor. Intrinsic contributions cluster sharply by crystal type (LSO 28–31 ps, GAGG 49–56 ps), exceeding the analytical CRLB by 1.42–1.62× due to DOI and transport effects. A walk asymmetry $\rho(\Delta T_E, dE)/\rho(\Delta T_T, dE)$ = 1.42–1.82× reflects front-end pulse-shape physics. The decomposition quantifies circuit-improvement leverage: LSO configurations retain 11–15% potential CTR reduction, while GAGG configurations operate within 2–6% of their photon-statistics bound. The framework provides a single-measurement diagnostic for prioritizing circuit-side versus detector-side investments in PET front-end development, and also provides the first quantitative noise-budget characterization of NUV-DJ SiPMs.

Abstract
Stacked scintillator configurations to obtain depth-of-interaction (DOI) information, combined with small crystal pitch, are commonly used to improve spatial resolution and maintain uniform performance across the field of view. Such configurations are prone to inter-crystal scatter (ICS), where energy deposition is shared across multiple crystals, leading to event mis-assignment and degradation of detector performance, including incorrect DOI estimation. Correction of these effects typically benefits from individual channel readout, which is often limited in highly multiplexed systems. In this work, we investigate ICS in a dual-layer LSO detector with 1.6 mm pitch, employing a 10×10/9×9 stacked crystal configuration coupled to a 4×4 SiPM array. The detector uses a highly multiplexed readout scheme with only three output channels (x, y, and total energy), imposing additional constraints on event discrimination. To analyze ICS effects, a hybrid simulation framework was developed, pairing Geant4-based modeling of gamma interactions with custom light transport and readout model. The simulations reproduce characteristic structures observed in experimental data, including patterns in floodmaps and energy-dependent light spread distributions. Based on these results, a light-pattern-based metric was introduced to identify ICS events using an energy-dependent threshold derived from single-interaction event distributions. This approach indicates that 32.9 ± 5.5% of events per crystal are affected by ICS and assigned to a non-optimal crystal, including mis-assignment between layers. Reassignment of these events to the most likely interaction crystal increased effective sensitivity by 4.1% and improved energy resolution from 10.6 ± 1.8% to 10.2 ± 1.8% FWHM. These results demonstrate that ICS as major effect in finely pixelated, DOI-capable detectors and that its identification and partial correction is feasible under highly multiplexed readout conditions.

Characterization of a multiplexed SiPM readout with free-running ADC for BGO PET detectors (#2466)

Nicola Belcari[1,2], Matteo Morrocchi[1,2], Giancarlo Sportelli[1,2]

[1] University of Pisa, Department of Physics "E. Fermi", Pisa, Italy; [2] INFN - Istituto Nazionale di Fisica Nucleare, Sezione di Pisa, Pisa, Italy

Abstract
We present a modular FPGA-based data acquisition and real-time processing architecture for SiPM-based PET detectors, developed in the context of compact, low-cost PET imaging. The system combines a multiplexed readout of a SiPM array with free-running high-speed ADCs and on-chip FPGA processing to extract event energy, timestamp, and interaction position in real time. The approach emphasizes compactness, scalability, and low-latency operation, while reducing channel count and system complexity. First measurements demonstrate correct operation and clear crystal identification in flood maps, highlighting both the potential and current limitations of

SiPM multiplexing, such as the limited CTR. This work aims to enable cost-efficient, flexible, and scalable PET imaging systems.

Evaluating a novel type of silicon photomultiplier for X-ray photon-counting CT applications (#2659)

Lukas Schröder, Marc Snoeyink, Dennis R. Schaart

Delft University of Technology, Radiation Science & Technology, Delft, Netherlands

We thank Broadcom Inc for providing the SiPM samples as well as preliminary PDE data. This work is partly funded by EU Horizon grant 101112053.

Abstract
Photon-counting computed tomography (PCCT) is a rapidly emerging (medical) imaging technology. PCCT commonly relies on finely pixelated room-temperature semiconductor detectors (RTSD). Scintillation detectors have long been considered too slow to handle the high X-ray fluence rates encountered in clinical PCCT. However, the fast signals provided by modern scintillators and silicon photomultipliers (SiPMs) allow us to reconsider this paradigm. SiPM-based scintillation detectors offer excellent image quality and are known to operate reliably in clinical time-of-flight positron emission tomography (TOF-PET) scanners. Recent research indicates that the combination of ultrafast SiPMs and scintillators could potentially provide a robust, scalable, and affordable X-ray photon-counting detector (PCD) technology. Here, we evaluate a novel type of silicon photomultiplier (SiPM) for this application. The SiPM is based on small (< 15 □m) single-photon avalanche diodes (SPADs), which have an innovative design that enables a fast recharge time (< 7 ns) as well as a high geometric efficiency (fill factor),

resulting in high photodetection efficiency (PDE) (~ 50%) over a broad wavelength range. These benefits can be exploited to mitigate the classical trade-off between dynamic range and PDE, which is of high interest for X-ray photon-counting applications. We perform experiments with different design variations of the new SiPM, coupled to small pixels of commercially available scintillators (e.g. LYSO:Ce, LaBr3:Ce). We report on the pulse shape, count-rate capability, and spectral performance achieved with different combinations of SPAD design and scintillator.

This research has been supported by Universidad Carlos III de Madrid through the Young Doctors Research Activity Grant

Abstract

This work presents the development of a semi-monolithic laser-engraved PET detector with dual-ended readout for continuous Depth of Interaction (DOI) estimation. The detector is based on a monolithic LYSO scintillator structured using Subsurface Laser Engraving (SSLE) techniques, enabling controlled light sharing between neighboring pixels while pre-serving the simpler readout and calibration typically associated with pixelated detectors, together with the accurate interaction vertex determination characteristic of monolithic designs. The main objective of this work is to determine the optimal placement of a reduced number of photodetectors in order to maximize DOI performance while minimizing the system's complexity. The study is based on the direct experimental measurement of light sharing inside the scintillator crystal. For this purpose, two 61- channel SiPM matrices are coupled to both faces of a LYSO scintillator matrix featuring a honeycomb laser-engraved pattern of 181 crystals. Taking advantage of the fact that the existing electronics can process up to 64 channels, the light distribution measured on one side of the detector is combined with the signal collected by only three selected photodetectors on the opposite side to estimate the DOI and evaluate different configurations for these additional channels. Using fully instrumented matrices on both faces allows the evaluation of different three-SiPM configurations and provides a detailed understanding of scin-tillation light-sharing behavior. The proposed approach aims to identify compact dual-ended configurations capable of achieving continuous DOI estimation with reduced readout complexity for future high-resolution PET detectors.

Abstract

We report updates on the development and current progress of PETVision, a modular flat-panel positron emission tomography (PET) system designed to achieve ultra-high Time-of-Flight (TOF) resolution. Traditional cylindrical PET scanners often face limitations due to high crystal volume costs and geometries that restrict simultaneous medical intervention. By leveraging unprecedented Coincidence Time Resolution (CTR), the PETVision architecture enables limited-angle, flat-panel geometries that reduce material costs while maintaining high image resolution.

The Photo-Detection Module (PDM) of the PET system is utilizing a 2.5D integration configuration, where Silicon Photomultiplier (SiPM) arrays and readout ASICs are coupled to opposite sides of a passive interposer. The sensing layer employs state-of-the-art NUV-HD-MT technology, featuring custom "glass-less" Through Silicon Vias (TSVs) to achieve a Photon Detection Efficiency (PDE) of up to 65% and a Single Photon Time Resolution (SPTR) with Full Width at Half Maximum (FWHM) as low as 20 ps. Readout electronics development is proceeding in two stages: an initial 32-channel FastIC+ BGA chiplet demonstrating a CTR of (85±1) ps FWHM with 2×2×3 mm3 LYSO:Ce:0.2%Ca scintillator crystals. This is followed by the 64-channel Positron Emission Tomography Integrated

Circuit (PoETIC) ASIC, which targets an electronics jitter contribution below 12 ps r.m.s. to support the 10-picosecond challenge. This modular approach aims to provide a high-performance, cost-effective PET imaging system suitable for diverse clinical and research applications, including simultaneous PET/intervention procedures.

Comparative Evaluation of NUV-MT and NUV-DJ SiPM Timing Performance for TOF-PET Detector Application (#3213)

Suhan Choi[1], Hyeong Seok Shim[1,2], Guen Bae Ko[1]

[1] Korea Advanced Institute of Science and Technology, Department of Nuclear and Quantum Engineering, Daejeon, South Korea; [2] Korea Advanced Institute of Science and Technology, Mechanical Engineering Research Institute, Daejeon, South Korea

This study was supported through the provision of NUV-DJ SiPMs by Broadcom.

Abstract

Recently developed Broadcom NUV-DJ SiPMs have improved photon detection efficiency (PDE) by placing the high-field region deeper than that of NUV-MT SiPMs. PDE is one of the major factors affecting coincidence timing resolution (CTR), and its performance varies depending on the scintillation light wavelength. Therefore, this study comparatively evaluated the CTR performance of LYSO:Ce, GAGG:Ce, and BGO scintillators, which have different peak emission wavelengths, coupled with NUV-MT and NUV-DJ SiPMs. The detectors consisted of 6 × 6 mm² NUV-MT and NUV-DJ SiPMs coupled with 3 × 3 × 20 mm³ LYSO:Ce and GAGG:Ce crystals and 3 × 3 × 3 mm³ BGO crystals using optical grease. Timing and energy signals were processed using a high-frequency (HF) readout board and acquired using an oscilloscope. CTR measurements were performed as a function of overvoltage for each detector. In addition, quartile-based rise-time analysis was conducted for the BGO detectors to investigate the effect of prompt Cherenkov photon detection on timing performance as indirect indicators. The detectors coupled with NUV-MT SiPMs achieved CTRs of 109.0 ps (LYSO:Ce), 182.8 ps (GAGG:Ce), and 210.8 ps (BGO) at an overvoltage of 12 V, whereas those coupled with NUV-DJ SiPMs achieved CTRs of 103.0 ps (LYSO:Ce), 172.4 ps (GAGG:Ce), and 187.2 ps (BGO), respectively. Compared with the NUV-MT SiPMs, the NUV-DJ SiPMs improved CTR by 5.2%, 4.5%, and 11.2% for LYSO:Ce, GAGG:Ce, and BGO, respectively. The quartile analysis further showed improved timing performance for fast rise-time events when using the NUV-DJ SiPMs. These results indicate that the improved PDE of the NUV-DJ SiPM enhances prompt photon detection and contributes to

improved CTR performance for BGO scintillators. Therefore, the proposed detector configuration may be beneficial for future TOF-PET and BGO-based timing detector applications.

Abstract

Monte Carlo simulations of optical photon transport are the gold standard for modeling PET detectors, but their step-by-step nature makes large-scale optical systems computationally prohibitive. Generative models are an attractive alternative, and we previously demonstrated conditional generative adversarial networks for single crystals and crystal arrays, in which physics knowledge enters the model through architectural extensions and a physics-informed loss. In this work, we propose a fundamentally different way of incorporating physics. Instead of acting on the loss, prior physical information is injected directly into the conditioning pathway of the generative model. A lightweight, geometry-agnostic light transport estimator (GALTE) propagates photons through the segmented crystal geometry under a simplified physical model and produces a compact descriptor of the expected sensor-level light response. This descriptor replaces the bare emission coordinates as conditioning input, leaving the generative model to capture only the residual stochastic structure that the analytical prior cannot resolve. We instantiate the framework with a conditional GAN whose architecture and trainable parameter count matches the published OptiGAN baseline, so that observed differences can be attributed to the conditioning rather than to model capacity. On a 3×3 BGO array, the GALTE-conditioned model preserves the distributional fidelity of the OptiGAN baseline across the full crystal array while reproducing physically interpretable structures of the joint position–momentum distribution more closely, particularly in regimes of high reflection multiplicity. Most notably, the GALTE-conditioned model reaches its best performance after roughly one third of the training epochs required by the OptiGAN baseline. Physics-informed conditioning thus opens a path toward generative models that combine physical priors with machine learning.

Abstract

Time-of-flight positron emission tomography (PET) timing calibration is especially challenging for light-sharing detectors, where biases arise from interaction-dependent light transport, silicon photomultiplier response, and effects of readout electronics. Conventional skew and walk corrections are robust but leave high-dimensional event signatures underused. We introduce an in-system approach that learns detector-wise corrections from coincidence data without requiring pair-specific models. A shared network conditioned by detector embeddings estimates single-interaction offsets from singles observables, yielding a structured model with linearly scaling detector-specific parameters. We evaluate the method on two prototype PET systems: a 24-module semi-monolithic detector scanner and a 28-module multi-layer segmented-crystal detector scanner. For both, data were acquired at 450 randomized 22Na point-source positions and split by source position for fivefold cross-validation. We studied a residual multilayer perceptron, a geometry-aware transformer, and a lightweight edge multilayer perceptron. Across scanners and energy windows, learned models improved coincidence timing resolution over time-skew and time-walk correction. The residual multilayer perceptron achieved the best timing resolutions, reaching 431ps and 382ps for scanners 1 and 2. Transformer and edge variants performed similarly with smaller models and generalized to detector pairs excluded during training. Feature ablation identified light spread as the dominant auxiliary cue, with local position and energy adding further improvements. These results establish detector-wise learning as a practical route to scalable timing calibration for PET systems with complex light-sharing detector topologies.

GPU-Accelerated Monte Carlo Simulation for SPECT Imaging (#1616)

Feng Zhou[1], Zhongzhi Liu[1], Yusheng Li[2], Bo Gao[1], Songsong Tang[1], Chen Sun[1], Liuchun He[1]

[1] United Imaging Healthcare, Shang hai, China; [2] United Imaging Healthcare North America, Houston, USA

Abstract

Monte Carlo simulation (MCS) is essential for PET and SPECT system modeling and optimization. However, existing CPU-based toolkits such as GATE and Geant4 remain too slow for iterative system design. We present a GPU-accelerated SPECT simulation module within the United-Imaging Healthcare (UIH) Molecular-imaging Innovation Platform (uMIP), extending its validated PET capability to single-photon imaging with native support for both multi-pinhole and parallel-hole collimator geometries. The key innovation is a closed-form analytic ray-aperture intersection algorithm for multi-pinhole collimators, which eliminates iterative geometric traversal and enables massively parallel GPU execution. Its speed is approximately 2~3 orders of magnitude faster than a CPU-based simulation toolkits. Quantitative validation against Geant4 demonstrates excellent agreement for both multi-pinhole and parallel-hole configurations: point-source projection profiles across six field-of-view positions yield NRMSE <0.80% and Pearson correlation >90%, while transmitted-photon spatial distributions and energy spectra show consistent results at both 140 keV and 440 keV. The proposed framework provides a practical, high-fidelity simulation platform for rapid SPECT collimator design and imaging protocol optimization.

Abstract

Accurate Monte Carlo simulation of Positron Emission Mammography (PEM) scanners is essential for optimizing detector design, reconstruction algorithms, and dosimetry in dedicated breast imaging. This work presents a GATE 9.4 simulation of the Naviscan PEM scanner validated against clinical sensitivity measurements at Hamad Medical Corporation, Doha, Qatar. Scanner geometry was implemented from published specifications, with detector efficiency derived from LYSO crystal attenuation via the Beer-Lambert law (approximately 70% for 13 mm crystals, mu = 0.86 cm-1 at 511 keV). A cylindrical aluminum sleeve phantom in five configurations (zero to four 2.5 mm sleeves) was simulated using a 0.58 ns coincidence timing window and a 350-650 keV energy window, matching the hospital protocol. True coincidences were counted following clinical convention, including scattered events within the energy window. The base-case configuration achieved 96.8% agreement with hospital measurements. Mean agreement across all five configurations was 70.3%, with the correct exponential attenuation trend reproduced across increasing sleeve thicknesses. Systematic underestimation at higher attenuation is consistent with known GATE aluminum cross-section limitations and the absence of scatter recovery corrections. All parameters were derived from first principles without empirical tuning. Preliminary results demonstrate a rigorous, reproducible simulation framework for PEM, with complete validation to be presented at the conference.

This work was supported by the JSPS Kakenhi grant number: 24K15805.

Abstract

This paper presents an optimization framework for Halbach magnet arrays targeting PET-compatible portable low-field MRI. Positioning an MRI system within existing PET rooms offers a practical alternative to PET-in-MRI inserts, as it simplifies compliance with radioisotope regulations. However, achieving high field uniformity in a 200-magnet Halbach array requires optimizing discrete rotation angles within an exponentially large search space. To address this, we developed a genetic algorithm (GA) utilizing adaptive mutation and dynamic elitism. To prevent premature convergence caused by rapid diversity loss in high-dimensional spaces, we investigated five population seeding strategies, including a novel Segmented Stochastic Progression (SSP) method using stratified complexity sampling. Performance was evaluated via fitness convergence and Hamming distance using progressive mutation step-size ranges (sigma = 6 to 1 and 10 to 1). Our results demonstrated that heuristic seeding maintained population diversity 1.3 to 2.6 times more effectively than random initialization. Specifically, the SSP method provided superior global search stability, yielding highly ordered magnetic flux streamlines across a 10 cm target region within a 20 cm diameter ring. Furthermore, mean time to solution (MTTS) remained consistent (0.94–1.00 relative to baseline), indicating the search quality was improved without increasing the computational overhead. This approach offers a robust, transferable methodology for complex electromagnetic design optimizations.

Experimentally Validated GATE Model of a Commercial PET System with Sub-200 ps TOF (#1879)

Michel Atieh[1,2], Emmanuel Durand[1,2], Olga Kochebina[2]

[1] Assistance publique – Hôpitaux de Paris (AP-HP), Department of Biophysics and Nuclear Medicine, Le Kremlin-Bicêtre, France; [2] Université Paris-Saclay, BioMaps Laboratory, Service Service Hospitalier Frédéric Joliot, CEA, Orsay, France

Abstract
This paper presents a GATE Monte Carlo model and its preliminary validation of the uMI Panorama 35™ PET system, which combines a 35 cm axial field-of-view with sub-200 ps time-of-flight performance. The model was validated for coincidence time resolution (CTR) and against NEMA NU 2-2018 measurements of sensitivity and noise equivalent count rate. The coincidence time resolution of 197 ps obtained with the model is comparable to 194 ps measured experimentally, and a system sensitivity of 21.0 versus 23.5 kcps/MBq. It also reproduced count-rate performance, with a peak noise equivalent count rate of 615 kcps at 43.7 kBq/mL, compared with 687 kcps at 43.2 kBq/mL experimentally. These results show the preliminary work on its validation and focuses mainly on the main counting performance characteristics of the scanner. Future work will extend validation to additional image tests, including spatial resolution and image quality.

Abstract
PET image quality depends on accurate identification of the gamma-ray interaction point. RETIMAGER proposes laser-engraved (LE) pixelated LYSO blocks, where inter-crystal transparency can be tuned through engraving density. This controlled light sharing can preserve crystal identification while providing XY position information. Previous GOSS optical simulations combined with artificial intelligence (AI) predicted the transparency range expected to optimize XY resolution for 1.25 mm pitch hexagonal crystals. Here, we extend this simulation-guided strategy to experimental data by analysing four LE matrices with different engraving densities and effective

transparencies. For each event, the seven largest SiPM signals were used to characterize the light-sharing pattern. A χ^2 classifier was developed from reference patterns associated with the two main configurations imposed by the hexagonal geometry: crystals above one SiPM and crystals close to a vertex shared by three SiPMs. GOSS simulations with different transparency values were processed with the same procedure and used to select a representative configuration and define the ROI criterion for extracting the χ^2 reference distributions. This criterion was transferred to the experimental matrix, separating the expected 1-SiPM-like and 3-SiPM-like populations. These results show that simulation-guided light-sharing analysis supports classification of the experimental response and future application of AI-based XY identification to LE matrices, aiming to determine the transparency that maximizes detector performance and enables intracrystal positioning.

Microstructure-Informed Single-Grid Dark-Field X-ray Imaging for Breast Microcalcification Typing (#2061)

Sunghoon Choi, Sora Park, Jun-Tae Kang, Jihwan Yeon, Jin-Woo Jeong

Electronics and Telecommunications Research Institute, Materials and Components Research Division, Daejeon, South Korea

This research was supported by the National Research Council of Science & Technology(NST) grant by the Korea government (MSIT) (No. CAP25021-000). This research was also supported by the National Research Foundation of Korea (NRF) funded by the Korea government (MSIT) (RS-2023-00302330).

Abstract
Dark-field X-ray imaging (DFXI) measures ultra-small-angle scattering from sub-resolution density fluctuations and provides contrast complementary to attenuation mammography. We present a wave-optics simulation of a compact single-grid spatial-harmonic imaging (SHI) DFXI system for breast microcalcification typing, focusing on type-II hydroxyapatite (HAp) and type-I calcium oxalate dihydrate (COD). Instead of a generic monodisperse-sphere model, the simulation uses a calibrated $\gamma(\xi)$-based microstructure interface: HAp is represented as a Gaussian-random-field medium, whereas COD is represented as a compact-crystal scatterer with weak surface-dominated dark-field response. For a 17.5 keV source, 20 μm focal spot, 47 μm grid period, and 2.0 m source-to-detector distance, the operating autocorrelation length is ξ_G=249 nm. Simulations with simplified Bakic-style Voronoi backgrounds over BI-RADS A--D show that large HAp clusters remain detectable under anatomy-limited conditions and that the dark-field-to-absorption ratio, $r=\Delta I_{df}/\Delta(1-T)$, separates HAp-like and COD-like clusters more robustly

than either channel alone. These results support compact tabletop SHI-DFXI for specimen-level microcalcification characterization and surgical-margin assessment.

Abstract
Total Body Positron Emission Tomography (TBPET) scanners offer a substantial sensitivity increase compared to traditional scanners, leading to lower doses or acquisition times. In parallel, interest in modelling such tomographs through Monte Carlo simulations has raised. In this work, a faster framework to simulate TBPET scans is presented by modelling the Siemens Biograph Vision Quadra scanner. SimPET platform is used for simulation, which

combines the use of SimSET and STIR. To assess its performance, spatial resolution, sensitivity and image quality NEMA tests were run. Spatial resolution shows reasonable agreement, with an average deviation of 0.6 mm. Although our model overestimates the experimental sensitivity, as expected for a simple cylinder model, a calibration factor is proposed. Concerning image quality, recovery coefficients align with experimental data, while background variability is higher due to reduced maximum ring difference. To sum up, our approach represents a faster alternative (projected x40 speed-up), which could make feasible the large-scale databases simulation when fully adjusted and optimized.

Performance Comparison of Low-Multiplexing and High-Multiplexing Multi-Pinhole Collimators for a Large-Animal Cardiac SPECT System

(#2308)

Jiali Yan, Debin Zhang, Weigang Duan, Shi Wang, Zhaoxia Wu, Hui Liu, Yaqiang Liu

Tsinghua University, Beijing, China

This work was supported in part by the National Key Research and Development Program of China (No. 2022YFC2402002, No. 2022YFC2403802), and National Natural Science Foundation of China (No. 12205166)

Abstract

Large-animal preclinical studies are essential for translating cardiovascular imaging technologies toward clinical applications; however, dedicated SPECT systems optimized for large-animal cardiac imaging remain limited. In this study, we propose a full-ring large-animal cardiac SPECT system composed of six detector heads and investigate

the impact of multi-pinhole multiplexing on system performance. Two collimator configurations are compared: a low-multiplexing reference design with 6 pinholes per plate and a high-multiplexing system with 36 pinholes per plate. The 36-pinhole configuration is generated using a Halton sequence, serving as a specific high-multiplexing representative rather than an optimized arrangement. System performance is evaluated using sensitivity maps and multiple digital phantoms, including a Defrise disk phantom for axial sampling assessment, a Derenzo phantom for spatial resolution evaluation, and a hot-sphere phantom for contrast analysis. All studies employ analytic projection and the Maximum Likelihood Expectation Maximization reconstruction. Results demonstrate that the high-multiplexing system achieves a higher peak sensitivity (2.04×10^{-3} vs. 3.87×10^{-4}), improved hot-rod resolution (3.5 mm clearly resolved vs. 4.5 mm marginally resolved), and a smaller detectable hot-sphere diameter (4 mm vs. 5 mm). In conclusion, high-multiplexing multi-pinhole design may benefit spatial resolution and detectability in stationary SPECT systems, although projection-overlap-induced artifacts must be carefully managed.

Is 20 mm Still Optimal? Revisiting Scintillator Length in Modern TOF-PET Systems (#2332)

Mizuki Furuta[1,2], Han Gyu Kang[1], Hideaki Tashima[1], Go Akamatsu[1], Taiga Yamaya[1]

Abstract
Scintillator length of 20 mm has been considered a standard in positron emission tomography (PET); however, recent advances in time-of-flight (TOF) performance necessitate a re-evaluation of this assumption. While shorter scintillators improve coincidence timing resolution (CTR) at the expense of detection efficiency, enhanced TOF information may compensate for this loss in terms of image quality. In this work, we experimentally investigated the effects of crystal thickness on CTR and performed simulations of a clinical PET scanner to evaluate image quality. We used fast-LGSO crystals with a cross section of 4 × 4 mm2 and varying lengths, each coupled to a silicon photomultiplier (SiPM; Hamamatsu Photonics) that had an effective area of 4.0 × 4.0 mm². The timing and energy signals of the SiPM were extracted using a custom-made high frequency readout circuit and digitized with a CAMAC digitizer. The measured CTRs of 10 mm, 15 mm, and 20 mm fast-LGSO crystals were 121 ps, 129 ps and 134 ps, respectively. Based on the experimental results, we investigated the effects of crystal thickness on the image quality of a clinical PET scanner (ring diameter= 675 mm, axial coverage= 158 mm) by Geant4 simulation. Image quality was evaluated using an IQ phantom based on the NEMA NU 2 standard, and metrics including

contrast recovery and background variability. Among the three crystal thicknesses, the 20 mm thickness provided the highest contrast while keeping the background variability. At this stage, we have concluded that longer scintillators appear to provide better image quality. We are still investigating the performance of even longer lengths such as 25 mm and 30 mm, and their performance will be discussed at the conference.

Abstract
Monte Carlo (MC) methods are powerful tools for simulating physical processing such as estimating in positron emission tomography (PET) scattered and true coincidences in PET, with GATE considered the gold standard. However, the high computational costs can limit its clinical applicability. SimSET offers a substantially faster alternative while retaining the key photon-interaction physics required for accurate PET simulation. In this work, we present a systematic concordance study between SimSET and GATE for the GE Omni Legend PET scanner geometry. The two simulators are compared across four metrics: sensitivity sinograms for the true coincidences, 2D energy spectra, trues-only reconstructed images, and scatter fraction, using a uniform cylinder and a realistic [18F]PE2I brain phantom as test cases. Strong agreement was observed across all metrics, with scatter fractions differing by less than 0.03 percentage points (25.65% vs. 25.63%). SimSET was found to be approximately ~59x times faster than GATE for almost equivalent simulation conditions. These results demonstrate that SimSET reproduces GATE outputs with high fidelity on this state-of-the-art scanner geometry, establishing it as an efficient and accurate platform for MC-based scatter estimation in clinical PET imaging workflows.

Hybrid Least-Square and k-Nearest-Neighbour Event Positioning for a Compact Gamma Camera with Monolithic NaI(Tl) Scintillator (#2718)

Xiao Zhang[1], **Yujin Qi**[2], Andrea Fabbri[3], Valentino O. Cencelli[3], Huifeng Zou[4], Jian Zheng[1], Qiang Du[1], Zhongyi Wu[1], Benjamin M.W. Tsui[5]

Abstract

The purpose of this study is to develop an accurate event positioning algorithm for a compact scintillation camera to enhance its intrinsic resolution and useful field-of-view (FOV). The compact camera consists of a 50×50×7mm^3 continuous NaI(Tl) crystal directly coupled to a Hamamatsu H12700 position-sensitive photomultiplier tube (PSPMT) with an 8×8 multi-anode readout array. Two kinds of reference libraries of detector responses for event positioning were built by analytical model of scintillation light distribution in a monolithic crystal and GENT4-based GATE Monte Carlo (MC) simulation, respectively. Each entry of the discrete grids-based library contains a detector response distribution corresponding to a known interaction position in crystal volume. Then a hybrid event positioning framework combining least-square estimation (LSE) and k-nearest-neighbour (k-NN) was developed and experimentally validated using Tc-99m flood sources. Preliminary test results show that the proposed hybrid event positioning method with MC simulation-based reference library exhibits good positioning linearity and edge-event positioning accuracy to enhance detector's spatial resolution and useful FOV as compared to the conventional centroid positioning method. Experimental results also demonstrate that the hybrid algorithm provides robust and computationally efficient event positioning. In conclusion, the approach combing hybrid algorithm with MC simulation-based reference library offers a practical and accurate solution for next-generation monolithic gamma-camera systems requiring high throughput and high intrinsic resolution. Further experimental evaluations are continued under investigations.

Abstract

Positron range (PR) degrades spatial resolution in positron emission tomography (PET), with its efect being radionuclide- and medium-dependent. Current accurate PR simulators are computationally intensive and cannot be used in clinical applications. This work presents the Hybrid Monte Carlo (HMC) PR simulator, a GPU-accelerated condensed-history code in CUDA Fortran for 3D annihilation imaging in heterogeneous voxelized geometries derived from CT images and μ-maps. Pre-computed interaction tables covering 24 reference-tissue materials and support for arbitrary β^+ emitters up to 3.55 MeV end-point energies (^{68}Ga, ^{82}Rb, etc.) allow both GPU and CPU implementations. Maximum speeds reach $4.77 \cdot 10^5$ (Intel Core i9-14900KF) and $3.32 \cdot 10^8$ (NVIDIA GeForece RTX 5080) histories/s, surpassing prior CPU-only PR simulators by up to 4 orders of magnitude. Close agreement with PenEasy 2024 is demonstrated: point-source simulations reach FWHM residuals are below 0.1 mm at 10^7 histories, and voxelwise R^2=0.982 and PSNR≈30.8 dB are achieved in a realistic myocardium phantom while decreasing the simulation time from 6 hours to 1 second (using HMC GPU). The resulting annihilation maps enable PET resolution modeling and patient-specific PR correction within clinically practical time frames.

Analytic Determination of Minkhole Collimator Sensitivity With Penetration (#3082)

Yusheng Li

United Imaging Healthcare North America, MI, Houston, USA

Abstract

Multi-pinhole collimation in single-photon emission computed tomography (SPECT) trades aperture penetration against sensitivity and spatial resolution. Closed-form analytic sensitivities with penetration are known for the circular pinhole and the rectangular pinhole (recthole), but not for the recently introduced minkhole: a Minkowski-sum aperture lofting a circular waist into a rectangular exit. We close that gap with three knife-edge closed forms—an Anger three-term penetration expansion, an exact on-axis Stieltjes form in elementary moment integrals, and a Stieltjes-corrected hybrid—anchored to a two-dimensional level-set integral as the point-source-exact reference. The three-term expansion shares the universal penetration-order scaling of the circular-pinhole and recthole results; the minkhole’s first-order coefficient carries a disk-rectangle Steiner cross-term that vanishes at the recthole limit and is structurally absent from the cylindrical circular pinhole. The on-axis Stieltjes route recovers the Metzler–Moore recthole closed form term-by-term as the waist radius vanishes. Validation against a three-dimensional ray-tracing reference on a 12-panel benchmark grid gives worst relative errors of 1.01% (Anger), 0.69% (hybrid), and 0.39% (level-set exact). The hybrid enables sub-millisecond sensitivity evaluation for minkhole-based SPECT system-matrix construction.

Abstract

Integration of Compton cameras (CC) with PET can be advantageous for multitracer imaging and to improve the resolution for simultaneous β^+-γ emitters. This technology is showing potential to become a viable option. The combination of PET and SPECT faces challenges due to collimation in SPECT and poor performance at high photon energies. CCs overcome this limitation and are more suitable for high-energy and multiple gamma emitting radiotracers. The IRIS group of IFIC (Valencia) has shown via simulations that combined CC and PET imaging of a Derenzo-like phantom with ^{89}Zr, ^{124}I, and both ^{18}F and ^{95}Tc is feasible, demonstrating the ability of Compton-PET to image multiple radionuclides. In continuation of this work, a performance evaluation of an experimental Compton-PET prototype is ongoing. An identical geometry is also studied through GATE simulations. The geometry consists of four identical detectors, of which two are combined as a CC and the other two are placed as PET detectors facing each other at either side of the geometrical center of the system. Image reconstruction is performed using a custom algorithm developed by the IRIS group. We present reconstructed images of a ^{22}Na source array obtained with the simulated Compton-PET system. Successful imaging results pave the way for subsequent laboratory testing of the Compton-PET system, enabling simultaneous β^+-γ and multitracer radionuclide imaging.

Abstract

Proton Computed Tomography (pCT) is an emerging imaging modality designed to reduce uncertainties in proton therapy planning by directly mapping the Relative Stopping Power (RSP) of tissues. This study provides a comprehensive performance evaluation of the INFN pCT prototype, focusing on experimental dosimetric characterization and the determination of noise scaling laws. Utilizing a silicon tracker and a YAG:Ce calorimeter, measurements were conducted at the APSS Trento center with a 211.2 MeV proton beam. Dosimetry performed with TLD-100 thermoluminescent dosimeters revealed an absorbed dose of 1.4–1.5 mGy per10^8 trigger events, resulting in a total dose of 11.6 mGy for a high-quality 9-rotation scan. The investigation into image noise demonstrated that the system operates in a purely statistical regime, with the standard deviation of RSP following the inverse square root of the product of dose and voxel volume. No significant additive noise floor was detected. Analysis identified a 1 mm³ voxel volume as an optimal benchmark, constrained by Multiple Coulomb Scattering physical limits. At this resolution, measured noise levels ranged from 0.3% to 0.7%, significantly outperforming the 1% clinical requirement. These results validate the system's ability to provide high-accuracy RSP maps at low patient doses.

Abstract

In PET/CT scanners the x-ray source is turned off during the PET acquisition for several reasons, including preventing saturation of the PET detectors due to pulse pile-up from lower-energy scattered x-rays. We conducted simulation and experimental studies to evaluate if there are operating conditions where simultaneous PET and CT imaging is feasible.

Simulation studies were used to estimate the flux and energy distribution of scattered x-rays for a dedicated breast PET/CT scanner using a tungsten x-ray tube operated at 65 kVp. The x-ray tube spectrum was used for tracking of x-rays scattered at roughly 90 deg into a PET detector. We also evaluated using metal filters in front of the PET detector to preferentially absorb the lower energy scattered x-rays. We then conducted experimental studies of 511 keV photon detection by a LYSO scintillator in the presence of scattered x-rays. The x rays were generated from a mammography scanner operated at 49 kVp. The scattering object was a water phantom in the mammography field of view. The PET detector was located at 90 deg to the x-ray beam direction. The outputs were evaluated in terms of timing and energy spectra.

The simulation studies indicated that for the CT and PET scanner geometry, the scattered x-ray flux was overall reduced by 90 %. The addition of 1 mm of Ag or Cu in front of the PET detector reduced the flux of scattered x-rays incident on the PET detector by 99.5% or 96.5%, while reducing the flux of 511 keV photons by only 9% or 16%. The experimental studies demonstrated the expected dominance of the scattered x-rays on the PET detector output. The use of 1 mm of Cu filtration restored the photopeak signal, except for the predicted 16% loss. Both simulations and experimental studies indicate that simultaneous PET and x-ray imaging may be possible under certain conditions of x-ray tube technique, scanner geometry, and pre-detector PET filtration.

Abstract

As innovative imaging tools, both X-ray dark-field and X-ray fluorescence imaging show significant potential for medical applications. However, each modality has technical trade-offs that can limit its effectiveness when used in isolation. While molecular imaging plays a crucial role in modern diagnostics by enabling early detection and personalized therapy, existing *in vivo* methods often suffer from low sensitivity, limited resolution, or high ionizing radiation exposure.To address these challenges, this proof-of-principle study proposes a hybrid approach leveraging the synergistic advantages of X-ray dark-field imaging (DFI) and X-ray fluorescence (XRF) imaging. DFI—characterized by high sensitivity to micro-level structural abnormalities at a low radiation dose—is utilized to identify targeted regions of interest (ROIs), thereby overcoming the inherent resolution and dose constraints of XRF. By confining XRF scans exclusively to DFI-guided ROIs, the distribution of molecular nanoprobes (nanoparticles) can be mapped with high precision. This approach ensures that the high radiation doses typical of body-wide nuclear imaging are restricted to localized areas, significantly enhancing patient safety. In this work, specifications for both modalities were investigated via simulations and experiments to establish optimal integration parameters. Subsequently, a CAD model was developed and implemented to assemble the final integrated setup.

Abstract

In this paper we will introduce a system for two-dimensional imaging of positron emission. It has been developed for the investigation of plant roots grown in rhizotrones. A rhizotron is a narrow, transparent flower pot that forces the roots to grow in a virtually two-dimensional manner. For this reason, a 3D reconstruction, as done in a PET scanner, is not necessary, and for a 2D projection two opposing planar detector heads are sufficient. The heads cover an area of 134x134 mm^2 and each contains 4096 LYSO scintillation crystals of 1.85x1.85x10 mm^3 each. Digital Silicon Photomultipliers (Philips DPC) detect the scintillation events which are stored as list mode data on disk and are already used to instantly visualize an online image of the activity distribution. We will present first images and characterize the system based on evaluation measurements.

Abstract

Zebrafish play an important role in biomedical research as a key vertebrate model for disease studies and drug screening; however, PET imaging has not yet been translated to this animal model. To fill this gap, the PET prototype MERMAID has been specifically conceived for imaging adult zebrafish and other small aquatic animals. Initial studies have proven the feasibility of the concept, as well as the need for anatomical reference information. For the latter, we are developing a cone beam CT system to be integrated into MERMAID. Challenges are the low soft tissue contrast in zebrafish and its small thickness, the attenuation of the water-filled imaging chamber, and potentially high radiation doses for the target animal. Although synchrotron radiation and contrast agents have both proved successful in providing high resolution and contrast zebrafish CT images, neither is suitable for our case, nor phase-contrast CT imaging techniques. The current CT setup consists of a cesium iodide flat panel detector and a handheld x-ray tube with a tungsten filament. For image reconstruction simultaneous algebraic reconstruction technique (SART) adapted from the reconstruction toolkit (RTK) is used. This setup allows a resolution smaller than 0.4 mm. We have successfully imaged several characterization phantoms as well as adult zebrafish ex-vivo, allowing visualization of the skeleton and small soft tissue changes in both air and water. Further work will include image registration, soft-tissue contrast enhancement, and integration with the PET component.

Abstract

This study presents an initial evaluation of a dual-panel PET prototype with TOF-DOI capabilities for high-resolution local human organs imaging. The system consists of two flat panel detectors, offering an open geometry suitable for small anatomical regions. Each panel has a 212 × 212 mm² active area and consists of dual-layer, multi-resolution LYSO detectors. An interleaved multiplexing circuit was implemented to reduce the readout channels by a factor of four, with signals processed by TOFPET2 ASIC electronics.

At the detector level, clear flood images were obtained with well identified crystals. The average energy resolutions were 14.60% and 14.09% for the top and bottom layers. The bottom layer achieved an average DOI resolution of 3.37 mm. The best coincidence timing resolution was 280 ps for bottom–bottom events after excluding inter-crystal scatter events. With a panel distance of 30 cm, the spatial resolutions at the center of the FOV were 1.15, 1.53, and 3.63 mm FWHM in the three orthogonal directions. The peak sensitivity was 4.29% at the FOV center and 2.14% at a 5 cm axial offset.

For phantom imaging, 1.6-mm rods were clearly resolved at the FOV center and remained discernible at a 5 cm off-center when four DOI bins were used in reconstruction. These initial results indicate that the dual-panel TOF-DOI PET prototype is promising for high-resolution imaging of localized human anatomy and small lesions detection. Its open and flexible geometry may also support dose monitoring in proton therapy. Further work will focus on correction methods, a more comprehensive performance evaluation, and practical imaging demonstrations.

Abstract

This work presents a Monte Carlo-based performance evaluation of a preclinical PET system based on a four-layer depth-of-interaction (DOI) detector. The detector with optimized layer thickness design comprises two LYSO arrays and two BGO arrays. The first and third layers adopt 60×30 LYSO arrays with pixel dimensions of 0.78×0.78×4 mm3 and 0.78×0.78×6 mm3, respectively, the second and fourth layers employ 40×20 BGO arrays with pixel dimensions of 1.21×1.21×4 mm3 and 1.21×1.21×10 mm3, respectively. System spatial resolution and sensitivity were characterized via Monte Carlo simulations following the NEMA NU 4 protocol. The single-ring system achieves the peak sensitivity of 16.6% and an average spatial resolution of 0.69 mm across the field of view (FOV). The complete dual-ring complete system could further improve the sensitivity to >25%. Compared with the two-layer detector system, the proposed four-layer DOI design exhibits significantly improved sensitivity while maintaining high and uniform spatial resolution. Experimental validation using the four-layer detector with total size of 51.6×25.8×25.5 mm3 demonstrated CNN classification accuracies of 84% for the LYSO layers and 76% for the BGO layers. Flood images using 45° oblique collimated incidence showed distinct event clustering patterns between upper- and lower-layers Future work will focus on developing the single-ring validation prototype and further improving the DOI layer discrimination accuracy.

Abstract

We report preliminary experimental results on the 3D imaging point spread function response performance of the Ultra-High Performance Brain PET (UHB-PET) system employing semi-monolithic LYSO slabs, machine-learning–based event positioning, and list-mode 3D point spread function (PSF) reconstruction. Detector calibration was previously performed using a slit-collimated 22-Na point source translated across monolithic and depth dimensions. A previous multilayer perceptron (MLP) estimated monolithic and depth positions of interaction, while axial positioning was derived via a previous center-of-gravity algorithm.

List-mode coincidence events were registered encoding time, energy, time-of-flight, module pair and within-module 3D coordinates, discretized into virtual detector pixels (50 transaxial × 50 axial × 20 depth) and mapped to global cylindrical coordinates after depth-of-interaction correction. A list-mode MLEM algorithm with an optimized Gaussian PSF model kernel width was employed. The system 3D imaging PSF was evaluated from 3-min acquisitions by placing a 0.25 mm 22-Na point source across 25 axial positions spanning the full axial FOV along the transaxial FOV center.

3D PET images free of visual artifacts were obtained. A uniform 3D PSF with mean relative absolute deviation from FOV center of 5.83%, 5.87% and 7.32% for both FWHM and FWTM was observed in radial, tangential and axial PSF components, respectively, across all axial locations demonstrating an axially homogeneous 3D imaging PSF for UHB-PET.

Ongoing work includes implementation of classification-based MLP positioning with improved detector resolution, incorporation of experimentally derived spatially variant PSF kernels, and validation with an extended set of phantoms to further optimize 3D imaging PSF response and its uniformity in all directions across the entire FOV.

Abstract

Our PET/MR breast insert currently under development is designed to be compatible with a whole-body 3T PET/MRI system. The proposed insert comprises a ring geometry based on dual layer LSO detector blocks coupled via FFC cables to SiPM arrays. Such integration in the confined and RF-shielded PET/MR environment introduces challenges related to thermal stability, which are addressed using data-driven temperature monitoring and correction. In an isothermal setup, the photopeak remains stable (898.7 ± 0.5). Under a temperature gradient, a drift from 901.1 to 914.1 (~ 1.1 to 8.5 keV) within 30 min is observed, resulting in a shifted and broadened energy spectrum (photopeak 907.8, FWHM 76.9). After scaling energy values via the derived ratio of the peak shift to the reference, the photopeak is restored to 899.1 with reduced FWHM (75.7). In parallel, combined operation of insert and whole-body PET systems requires alignment of independent timestamp domains to enable mixed-coincidence reconstruction. Two detector blocks were operated with independent local clocks, a synchronized reference was established and desynchronized by introducing a delay. A data-driven algorithm estimates this offset via a sliding-window coincidence search (±100 ns), where the offset is determined by the maximum coincidence counts within the timing window. After correcting for the delay, time difference spectra within a narrow ±3 ns time window could be restored while preserving a 430 ps coincidence resolution time. These results demonstrate that data-driven correction and synchronization enable stable PET/MR operation and potentially enable mixed-coincidence imaging across independent systems. Future work will focus on scaling to multi-ring systems, enhancing in-situ temperature sensing during MR operation, and evaluating mixed-coincidence imaging between independent PET systems enabled by the proposed synchronization approach.

Abstract

Conventional brain PET imaging of small rodents necessitates anesthesia to prevent motion artefacts. However, anesthesia may alter brain function and preclude the simultaneous assessment of brain function and animal behavior. The Motion-Adaptive Molecular and Behavioral Observation (MAMBO)-PET system aims to overcome these limitations by enabling brain imaging in awake, freely moving mice. The system consists of four detector panels. Two panels have been assembled, while the remaining two are in the final stages of assembly. Here, we report the initial performance of the two-panel MAMBO-PET system. The mean detector panel energy resolution ranged from 14.9% to 15.0%. The FWHM of the radial and tangential PSF profiles at the center of the FOV were 0.9 mm and 5.7 mm, respectively. Future work includes the NEMA characterization of the full 4-panel system.

First experimental and phantom results of the DC-SPECT scanner: a cardiac-dedicated SPECT with Laser-Processed CsI:Tl Detector Modules (#2799)

Xi Zhang, Arkadiusz Sitek, Mark P. Ottensmeyer, Fang Han, Hamid Sabet

Harvard Medical School, Massachusetts General Hospital, Boston, USA

This work was supported in part by NIH Grant No. R01HL145160 and R01EB034785.

Abstract

Our group is developing Dynamic Cardiac SPECT (DC-SPECT) featuring laser-processed CsI: Tl scintillators with converging pixels to avoid depth-of-interaction blurring. This work reports, for the first time, the initial imaging performance of the DC-SPECT scanner featuring laser-processed CsI: Tl detector modules with converging pixels. A 50×50×8.05 mm^3 CsI: Tl crystal was laserprocessed into a 25×25 converging-pixel array. The crystal was coupled to an 8×8 multi-pixel photon counter array , read out by a custom 64-channel analog front-end board and a 12-bit waveform digitizer. Three decoding algorithms were evaluated: MLE-Bicubic, MLE-Nearest, and a deep neural network (NN) decoder. A ^{57}Co point source and a ^{99m}Tc three-line source phantom were imaged using list-mode MLEM reconstruction. For the point source, FWHM values of 6.24, 6.58, and 5.67 mm were obtained for MLE-Bicubic, MLE-Nearest, and NN at 20 iterations, with NN yielding the sharpest response. At 50 iterations, FWHM values improved to 4.63, 4.98, and 5.02 mm, with MLE-Bicubic achieving the sharpest response. For the three-line source phantom, sources located near the center of the field of view yielded mean FWHM values as low as 3.55 mm (NN) and 4.04 mm (MLE-Bicubic). Sources near the field-of-view edge exhibited broader responses, consistent with the known degradation of detector sensitivity toward the detector periphery. The converging-pixel architecture effectively eliminates depth-of-interaction ambiguity without additional hardware, further supporting the practical viability of this detector design. Future work will focus on optimization of reconstruction parameters, and further phantom and cardiac imaging studies toward clinical deployment of the DC-SPECT system.

Abstract

Accurate geometric calibration is essential for high-resolution 3D PET image reconstruction because detector element mispositioning can introduce spatial misalignment of lines-of-response (LORs) and image blur. This challenge is particularly important in rotating flat-panel PET scanners, where opposing detector panels rotate during acquisition to improve angular coverage and enable fully 3D reconstruction. In this work, we developed and evaluated an image-based calibration method for estimating linear offsets between detector centers and the axis of rotation in the Radialis PET Imager, an organ-targeted rotating flat-panel PET scanner. The calibration was performed using a ^{22}Na point source acquired with twelve step-and-shoot detector rotations from -90° to +75°. Four point source experiments were performed at different source locations. An iterative algorithm was implemented to estimate linear offsets by minimizing distances between reconstructed point sources from different detector angles and the target image acquired at 0°. The estimated offsets were fed into transformation matrices used for composite image reconstruction of list mode data from all detector angles. Performance was evaluated using spatial resolution measurements from composite images, Hoffman brain phantom scans, and a clinical ^{18}F-Florbetaben brain scan. Offset calibration improved the average spatial resolution (FWHM) from 3.3 mm to 2.9 mm, with axial FWHM improving from 5.2 mm to 3.0 mm. Hoffman phantom images reconstructed with offset calibration demonstrated improved contrast and visualization of internal structures. The calibration of ^{18}F-Florbetaben clinical brain images demonstrated improved visualization of anatomical features, including the septum pellucidum, as well as improved contrast and reduced apparent cortical tracer uptake relative to image reconstructed without offset calibration.

Abstract

Compact PET scanners based on highly integrated front-end ASICs require stable thermal conditions to preserve detector gain, timing response, energy resolution, and inter-module uniformity. This is especially relevant in low-footprint PET systems, where high channel density and closed mechanical integration limit conventional forced-air cooling.

This work presents a thermal stabilization strategy designed for a new family of clinical and preclinical PET scanners: BuckyPET, BrainPET and UltraPET. The solution combines adaptive SiPM bias compensation with active liquid cooling of the ASIC electronics using a cascade proportional--integral (PI) controller. The outer loop regulates an exponentially filtered high-percentile aggregate of ASIC temperature deviations from a learned baseline, while the inner loop controls the coolant temperature through the chiller command. Saturation, setpoint slew-rate limiting and anti-windup mechanisms are included to improve robustness under variable conditions.

The proposed strategy maintained the ASIC thermal deviation within the tolerance band for different ambient conditions and high data throughput acquisitions. Preliminary measurements show improvements of up to 15% in energy resolution and up to 8% in coincidence time resolution compared with worst-case thermal drift conditions. The architecture enables compact, silent, and patient-friendly scanner designs, while preserving reproducible PET performance.

Abstract

Correcting counting loss phenomena caused by pulse pile-up and dead time is essential for the medical application of an energy-resolving photon counting detector (ERPCD). At the IEEE 2025 MIC conference, we proposed a counting loss correction algorithm applicable to objects, but it was limited to an effective atomic number (Z_{eff}) of 7–13. In this study, we propose a novel counting loss correction algorithm that extends the target object to Z_{eff} = 3–20 to cover biological samples, and evaluate the quantitative performance of the Z_{eff} images related to the algorithm. The novelty is to estimate the effect of counting loss on objects with Z_{eff} = 3–20 using experimentally derived counting loss correction functions for polymethyl methacrylate (PMMA, Z_{eff} = 6.5) and aluminum (Al, Z_{eff} = 13). Using the correction function for each Z_{eff}, the measured counting rate can be converted to the expected counting rate under ideal conditions without counting loss. Since the Z_{eff} of the object is unknown at the beginning of the analysis, corrections for Z_{eff} = 3–20 are tentatively performed. The corrected counting rate is then applied to the material identification algorithm, which was proposed in a previous study, and Z_{eff} is derived. Finally, the Z_{eff} of an object is determined when the entire algorithm works properly. To demonstrate our method, reference samples with known Z_{eff} (PMMA, Al, bilayer structures of PMMA and Al, and Si powder) and tooth samples were measured using a prototype ERPCD system equipped with a cadmium zinc telluride (CZT) semiconductor detector. When applying the correction to the measurement of reference samples, the accuracy of the Z_{eff} image was +/-1 under general radiography conditions. For a dental sample, tooth structure and resin can be observed with proper Z_{eff}. This result demonstrates that counting loss correction is important for the clinical application of ERPCD.

Abstract

Photon-counting CT (PC-CT) enables acquisition of energy-resolved images. Analyzing these images provides potential for quantitative diagnosis based on material composition. This study aims to develop an algorithm that simultaneously generates effective atomic number (Z_{eff}) and effective mass density (ρ_{eff}) images from virtual monoenergetic images (VMIs) acquired by clinical PC-CT. To demonstrate the feasibility of our algorithm, phantom experiment and clinical lung datasets were analyzed as representative applications. In our algorithm, Z_{eff} and ρ_{eff} values are estimated voxel-wise from two VMIs. The CT values are converted to μ values, and their ratio is converted to the Z_{eff} value using a reference curve created from a known database of mass attenuation coefficient (μ/ρ). In addition, the tentative mass densities as a function of atomic number are estimated by fitting μ/ρ data of each atomic number to the measured μ values, and the ρ_{eff} is uniquely determined using the Z_{eff} information. The algorithm was validated using an in-house low-density phantom and clinical chest CT images from 10 patients. We analyzed Z_{eff} and ρ_{eff} values in diseased and normal lung tissue regions. From the phantom study, the measured ρ_{eff} values were consistent with the reference density of the samples. In clinical analysis, lung diseases exhibited characteristic changes in ρ_{eff}. A metastatic lung nodule showed a similar Z_{eff} value compared to normal lung tissue,

but its ρ_{eff} value was clearly higher. During pneumonia follow-up, ρ_{eff} values decreased by approximately 56% after one month of disease regression, while Z_{eff} values remained nealy unchanged. Our algorithm generates Z_{eff} and ρ_{eff} images from PC-CT data, allowing quantitative interpretation of conventional CT values. These results suggest that ρ_{eff} provides a useful quantitative indicator for lung lesion assessment.

Dual-Energy CT Metal Artifact Reduction Using VMI-Guided Iterative Reconstruction Refinement (#1325)

Sungmin Park, Younghwan Lim, Soohyun Lee, Hyosung Cho

Yonsei University, Department of Radiation Convergence Engineering, Yonsei University, Wonju, South Korea

Abstract

Metal artifacts in computed tomography (CT) degrade image quality and reduce quantitative reliability, particularly in the presence of metallic objects. Conventional metal artifact reduction (MAR) methods, such as sinogram interpolation and normalized correction, rely heavily on accurate metal segmentation and often fail to preserve fine anatomical structures. Although dual-energy CT (DECT) provides additional spectral information for material characterization, its potential has not been fully utilized in prior-guided iterative MAR frameworks. In this study, we propose a prior-guided iterative MAR method for DECT that incorporates virtual monoenergetic image (VMI) priors for improved artifact suppression and structural preservation. Metal regions are first identified in the image domain using residual-based metal segmentation from initial dual-energy reconstructed images, and the resulting metal mask is forward-projected to generate the metal trace in the projection domain. Dual-energy projection data are then corrected in the projection domain using prior-guided interpolation to reduce metal-induced inconsistencies. Material decomposition is then performed to generate VMIs, which provide structurally consistent priors for subsequent image-domain reconstruction refinement. The final images are obtained by iterative prior-guided reconstruction that enforces data consistency while incorporating VMI-based edge guidance and artifact-suppression regularization to suppress residual artifacts and preserve anatomical boundaries. Quantitative evaluations on simulated datasets demonstrate that the proposed method significantly reduces root mean square

error and improves structural similarity compared with normalized MAR. These results indicate that the proposed framework effectively suppresses metal artifacts while maintaining structural fidelity and quantitative accuracy.

Abstract

Accurate BMD measurement is essential for osteoporosis diagnosis and fracture risk assessment. Wide fan-beam DXA systems provide faster scan acquisition than pencil-beam systems; however, their geometric characteristics can introduce magnification errors when the distance between the X-ray source and the subject changes. These distortions affect bone mineral content (BMC), projected bone area, and ultimately BMD accuracy. The iNSiGHT C510 (OsteoSys Co., Korea) employs a 25° fan beam with a SID distance of 812 mm, substantially wider than the 4.5° narrow fan beam geometry of the PRIMUS, which operates at a 634 mm SID. To compensate for magnification-induced distortion, the iNSiGHT C510 incorporates the geometric correction within the LUCIDA software platform. The correction algorithm was evaluated using a custom lumbar spine phantom elevated from 0 to 200 mm above the tabletop in 10 mm increments, with 10 repeated measurements obtained at each height. Without correction, the iNSiGHT C510 showed BMD deviations ranging from approximately +40% to −40%. After applying the correction algorithm, residual BMD variability was reduced to within ±5%, comparable to the ±4–5% variation observed with the PRIMUS under identical conditions. Correlation analysis between corrected iNSiGHT C510 measurements and corresponding PRIMUS values demonstrated strong agreement, with a coefficient of determination (R^2) of 0.934 and a standard error below 2%. These results indicate that the proprietary correction algorithm effectively compensates for magnification errors inherent to the wide fan-beam geometry, enabling the iNSiGHT C510 to achieve clinically equivalent BMD accuracy suitable for routine bone density assessment.

Transient radiative transport equation solution for ToF-CT ballistic X-ray photons (#2208)

Maëlle Fromont[1,2], Réjean Fontaine[1,2], Yves Bérubé-Lauzière[1,2]

[1] Université de Sherbrooke, Département de génie électrique et de génie, Sherbrooke, Canada; [2] Université de Sherbrooke, Institut interdisciplinaire d'innovation technologique - 3IT, Sherbrooke, Canada

Abstract

Computed tomography (CT) has made significant advances in reducing X-ray exposure while preserving image quality. A novel project to improve CT imaging involves subsituting anti-scatter grids with filtering out scattered photons using time-of-flight (ToF) measurements. A first approach resorting to ToF filtering was developed to eliminate the noise due to scattered photons, thereby improving the contrast-to-noise ratio. Additionally, ToF-CT has the potential to exploit both detected ballistic and scattered photons for reconstructing both 3D images of absorption and scattering using model-based image reconstruction.

In this approach, an X-ray radiation propagation model must be resorted to.

For this purpose, a transient radiative transport equation is presented herein. It is divided into ballistic and scattering propagation components. The present study focuses on the ballistic component, with the aim of evaluating various numerical methods to achieve better numerical temporal accuracy.

Abstract

The easyPET/CT is a multimodal imaging system that integrates positron emission tomography and computed tomography (CT), using LYSO:Ce scintillator crystals coupled to silicon photomultipliers. CT acquisition is done in photon-counting (PC) mode, enabling energy discrimination and improving contrast-to-noise ratio. The radiation source used is a ^{241}Am radioactive source (2.89 MBq), which simplifies system integration. This work presents the first characterization of the integrated CT modality of the easyPET/CT of through simulation, evaluating CT number calibration, noise, and uniformity. A non-linear system response between pixel intensity and Hounsfield units was observed and successfully corrected using a second-order polynomial fit (R^2=0.99). Noise and uniformity assessment revealed peripheral non-uniformity attributed to reconstruction artifacts. Spatial resolution characterization is ongoing. These results establish a foundation for a compact, portable PCCT system with strong potential for multimodal preclinical imaging applications.

Abstract

This work characterizes the LYSO:Ce/SiPM detector array of the easyPET/CT, a compact multimodal preclinical imaging platform. The characterization of the 16×2 array of LYSO:Ce crystals, coupled one-to-one to SiPMs was assessed per crystal in terms of energy resolution (ER), count rate, and sensitivity using a ^{241}Am radioactive source (59.5 keV). The mean ER was 33.8 ± 1.8% FWHM at 59.5 keV, competitive with current LYSO:Ce-based photon-counting detector systems reported in the literature. The mean count rate and sensitivity were 62.4 ± 5.3 photons/s and 0.7 ± 0.1 counts•photon^{-1}, respectively, both displaying a uniform spatial distribution across the array. The overall uniformity of the detector response validates the shared PET/CT hardware architecture as a viable approach for photon-counting CT, confirming that using the PET detector for CT operation preserves detector integrity. Future work will address pile-up characterization at higher count rates to further define the dynamic range of the system.

Abstract

Attenuation correction (AC) is crucial for artefact-free PET/MR images. Currently, CT-derived PET attenuation maps (AMs) are based on transformation schemes from conventional CT scanners with data from polyenergetic X-ray spectra. It is known that converting from polyenergetic CT image data to monoenergetic 511 keV linear attenuation coefficients (LACs) introduces systematic errors in the LACs employed for AC in PET imaging. To address this issue, we investigated spectral CT to obtain more accurate AMs. Spectral CT offers advantages over conventional CT scanners by providing the possibility of material decomposition. It also allows to reconstruct virtual monochromatic images (VMI) from the inherently multiple polyenergetic data sets of CT. The spectral information can also be used to obtain virtual non-contrast (VNC). In our approach, we use angiographic spectral CT scans with an administration of iodinated contrast agents and computed VNC images from the obtained dataset. The linear transformation scheme from monochromatic CT images to LACs at 511 keV was obtained from VNC images for different tissue types using an electron density phantom and a photon counting (PC) CT scanner. The use of VNC images effectively simplifies the transformation from HUs to LACs requiring only a single linear function. It further minimizes residual deviations of the LACs for soft-tissues mimicking materials. Deriving the LACs from VNC images instead of standard CT images may lower the systematic errors of CT-based attenuation correction for PET scanners equipped with dual energy CT systems.

Abstract

X-ray fluorescence computed tomography (XFCT) enables nanoparticle imaging and biological function imaging without radioisotopes. We successfully improved image quality by applying Deep Image Prior (DIP), a self-supervised deep learning technique that does not require training datasets, to XFCT images. However, conventional DIP, which uses randomly generated input images, has problems such as reduced spatial resolution and deviation from the true image distribution. To address these problems, we propose CT-DIP, a modified DIP framework in which the network input is replaced with projection images acquired from simultaneous X-ray transmission computed tomography (XTCT). Monte Carlo simulations using Geant4 were performed to generate both XFCT and XTCT projection images of a mouse brain phantom, with iodine used as a contrast agent to mimic cerebral blood flow. Image reconstruction was carried out using the ordered subsets expectation maximization (OS-EM) algorithm after DIP denoising. Visual evaluation and quantitative evaluation using Peak Signal-to-Noise Ratio (PSNR) and Structural Similarity Index Measure (SSIM) demonstrated that CT-DIP outperformed conventional DIP, Gaussian filtering, and only OS-EM reconstruction. Furthermore, CT-DIP reduced training time from 75.3 minutes to 4.2 minutes, representing an approximately 18 times speedup. These results suggest that CT-DIP has strong

practical potential for XFCT imaging in low-count environments, and future work will focus on validation with real measurement data.

Experimental Characterization and Materials-Driven Optimization of Fine-Pitch CZT Detectors for Photon-Counting CT (#2994)

Aziz Ikhlef, Salmon Arnab, Randy Luhta, Steve Utrup, Chris Vrettos

Analogic Corporation, Salem, USA

The authors acknowledge the support of Analogic Corporation and collaborating research partners.

Abstract
The performance of fine-pitch cadmium zinc telluride (CZT) photon-counting detectors is strongly governed by experimentally measurable charge transport and leakage current characteristics. We present the fabrication and experimental characterization of a pixelated CZT detector array with a nominal pixel pitch of 441 × 441 μm², targeting high-channel-count architectures for computed tomography (CT). CZT material properties were characterized using a custom-built time-of-flight (TOF) measurement system to extract electron mobility and lifetime under controlled electric field conditions. Dark current behavior was systematically measured as a function of bias voltage and pixel geometry to assess operational limits imposed by material quality. Experimentally derived transport and leakage parameters were used to perform a detector-level trade-off analysis linking CZT material properties, pixel pitch, and bias field. The results establish experimentally grounded constraints and design guidelines for scaling CZT detector arrays toward advanced photon-counting CT systems.

Abstract

Cross-modality synthesis from cone-beam CT (CBCT) to CT is central to online adaptive radiotherapy and accurate dose recalculation. Although planning MRI provides valuable soft-tissue information, daily CBCT captures the patient's updated anatomy on the treatment couch. Its direct use remains limited by scatter artifacts and imperfect Hounsfield Unit (HU) calibration. This study investigates whether aggregating sequential on-treatment CBCTs improves deep learning-based synthetic CT (sCT) generation compared with single-fraction CBCT or static MRI priors alone.

We developed a conditional GAN with Residual-in-Residual Dense Blocks to generate high-fidelity sCTs. The model was evaluated on 190 patients with brain metastases, split into 152 training cases and 38 independent test cases. Each patient had a planning CT used as ground truth, a planning T1-weighted MRI, and up to three daily CBCT scans. Four input settings were compared: 1 CBCT, 1 CBCT+MRI, 3 CBCTs, and 3 CBCTs+MRI.

Adding temporal and multimodal information improved sCT accuracy. The single-CBCT baseline achieved 67.79 HU MAE and 29.12 dB PSNR, while the full 3 CBCTs+MRI configuration reached the best performance, with 59.81 HU MAE and 30.82 dB PSNR. Importantly, temporal accumulation alone using 3 CBCTs achieved 60.01 HU MAE, outperforming the static multimodal 1 CBCT+MRI setting at 65.98 HU. This suggests that longitudinal CBCT redundancy provides stronger density and attenuation constraints than a single CBCT complemented by a rigid planning MRI prior.

Sequential CBCT aggregation, especially when fused with MRI, improves HU calibration and reduces daily setup artifacts, supporting robust automated sCT generation for online adaptive radiotherapy.

Abstract

Photon counting computed tomography (PC-CT) enables energy-resolved imaging and material-specific analysis through individual X-ray photon detection. In this study, dynamic hepatocyte-specific imaging was performed in healthy and liver tumor mouse using a developed two-dimensional (2D) PC-CT system consisting of a 16 × 64-channel YGAG scintillator array coupled with MPPC array, with a voxel size of 1×1×1 mm^3. Gd-EoB was intravenously administered, and time-resolved imaging was conducted before and after contrast injection. Reconstructed CT images in the 50–60 keV energy range and estimated Gd concentration maps were evaluated around the liver and bladder regions. Dynamic enhancement was observed after Gd administration in both healthy and liver tumor mice, with differences in temporal enhancement behavior and estimated Gd concentration tendency between the two models. Although the tumor region was not clearly distinguishable because of its small size and current image quality limitations, temporal changes in CT value and estimated Gd concentration were still observable. MRI comparison demonstrated a positive relationship between MRI signal intensity and PC-CT-derived Gd concentration, although quantitative tendencies differed because of differences in imaging mechanisms and contrast sensitivity between MRI and PC-CT. These results demonstrate the feasibility of scintillator-based PC-CT for dynamic hepatocyte-specific imaging in vivo.

Improved Material Decomposition Method in DXA Using Scatter-Induced Arrival Time Difference (#3163)

Sena Kwon, Jiwoong Jung, Sang-hyun Chun, Jiwon Nam, Jin Ho Jung, Yong Choi

Sogang University, Department of Electronic Engineering, Intelligent Signal Processing System (ISPS) Laboratory, Seoul, South Korea

This research was supported by the Industrial Technology Innovation Program funded by the Ministry of Trade, Industry and Energy (no. P0030253), by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (no. RS-2023-00280177), and by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (no. RS-2026-25565373) of the Republic of Korea.

Abstract

Material decomposition is commonly based on the R-value, defined as the ratio of attenuated intensities measured at low-high X-ray energies. However, materials with similar compositions, such as fat and muscle, can exhibit overlapping R-values, limiting the accuracy of material decomposition. This study investigates the feasibility of improving material decomposition using scatter-induced arrival time difference. Scattered photons travel longer paths than primary photons, resulting in delayed arrival times. Photons with arrival time delay exceeding a threshold were distinguished as scattered photons. The scatter ratio (SR), defined as the ratio of scatter counts in low to high energy regions, was used for an additional identifier for material decomposition. DXA system was simulated using GATE with a detector consisting of 240 × 24 LYSO pixels with dimensions of 3 × 3 × 5 mm^3, an X-ray source operated at 83 kVp and 0.2 mA with a 0.025 mm Ce filter, and the source-to-detector distance set to 1000 mm. Fat, muscle, and bone phantoms were placed at the center between the source and detector. The arrival time delay threshold was set to 20 ps since the maximum time difference of direct photons within the 5 mm pixel depth is 16 ps under ideal timing resolution of 0 ps. Each material was represented in feature space using the R-value and SR. Material separability was evaluated using a separability index based on the difference between feature means and standard deviations. In the feature space, fat, muscle, and bone formed distinct clusters. SR derived from photon arrival time difference improved the separability index for all material pairs. For fat–muscle, the separability index increased from 13 to 17, achieving a 25% increase. For fat–bone and muscle–bone pairs, separability improved by 84% and 62%, compared with the R-value. These results demonstrate the feasibility of improving the material decomposition in DXA using scatter-induced arrival time difference.

Limited-Angle and Few-View Image Reconstruction Using Point Spread Functions (#1111)

Gengsheng Zeng[1,2]

[1] Utah Valley University, Department of Computer Science, Orem, USA; [2] University of Utah, Radiology, Salt Lake City, USA

This work was supported in part by the National Institutes of Health under Grant R15EB024283.

Abstract

Limited-angle tomography and few-view tomography are extremely ill-conditioned problems. A usual way to reconstruct an image in limited-angle tomography or in few-view tomography is via an iterative algorithm that minimizes a two-term objective function. The objective function consists of a data fidelity term and a Bayesian term. A common Bayesian term is the total variation (TV) norm of the image. This paper proposes a different way to reconstruct the image in limited-angle tomography and few-view tomography by iteratively deconvolving the point spread function (PSF). Two PSFs are considered: the PSF of the filtered backprojection (FBP) and the PSF of pure backprojection. The method of using the PSF of pure backprojection gives better results.

Accelerating CGCIS Iterative Reconstruction Based on Location Priors from the DBP Algorithm (#1203)

Kui Wang[1], Yangyang Zhao[1], Shuyu Xu[1], Zhongbin Hang[2], Hui Liu[3], Jing Wu[4], Yaqiang Liu[3], Zuoxiang He[2], Qingyang Wei[1]

[1] University of Science and Technology Beijing, Beijing Engineering Research Center of Industrial Spectrum Imaging and School of Automation and Electrical Engineering, Beijing, China; [2] Tsinghua University, Beijing Tsinghua Changgung Hospital, Beijing, China; [3] Tsinghua University, Department of Engineering Physics, Beijing, China; [4] Beijing Normal University, Center for Advanced Quantum Studies, School of Physics and Astronomy, Beijing, China

Abstract

To address the high computational complexity and low efficiency caused by traversing all field-of-view (FOV) voxels during image reconstruction in full-ring cascade gamma coincidence imaging systems (CGCIS), we propose a location priors algorithm to significantly accelerate image reconstruction. By restricting system matrix calculations, forward projection and back-projection operations to the ROI. This reduces the computational complexity from $O(N_x \times N_y \times N_z)$ to $O(m \times n \times l)$, thereby significantly improving reconstruction efficiency. Experimental results demonstrated that, compared to conventional iterative algorithm, the proposed location priors algorithm achieved an approximate 37.05-fold acceleration in reconstruction speed while preserving high imaging quality. Ultimately, this advancement provides robust technical support for real-time, dynamic imaging monitoring utilizing theranostic nuclides.

DeepDreaming SPECT: Gradient-Based Reconstruction via Differentiable Physics Simulation (#1364)

Francesc Massanes

Siemens Medical Solutions USA Inc, MI SPECT Research, Hoffman Estates, USA

Abstract

We present a gradient-based SPECT reconstruction framework that treats the physics-based forward model as a frozen differentiable operator and optimizes the 3D activity volume through backpropagation, an approach directly analo gous to Google's DeepDream algorithm. The forward model is implemented as a PyTorch module comprising gantry rotation via trilinear interpolation, photon attenuation correction, and depth-dependent detector blur via per-slice convolution with measured point response function (PRF) kernels. Reconstruction minimizes the Mighell modified chi-square, a Poisson-appropriate cost function, using adaptive gradient descent. We evaluate four first-

order optimizers (Adam, AdamW, RMSprop, SGD) on a hot/cold sphere phantom acquired on a Siemens Symbia Intevo with LEHR collimation and demonstrate that RMSprop achieves the fastest cost reduction. Preliminary reconstructions at 20 iterations recover the phantom geometry with visible hot sphere contrast, validating both the forward model accuracy and the gradient-based reconstruction pipeline.

Plug-and-Play Learned Regularization in PET Reconstruction: Integration of DeepInverse and STIR through SIRF (#1578)

Kathiresan Chandrasekaran[1], George Webber[2], Alexander Denker[3,4], Matthias J. Ehrhardt[5]

[1] University of Bern, Department of Nuclear Medicine, Inselspital (Bern University Hospital), Bern, Switzerland; [2] King's College London, School of Biomedical Engineering and Imaging Sciences, London, UK; [3] Deutsches Elektronen-Synchrotron DESY, Helmholtz Imaging, Hamburg, Germany; [4] University College London, Department of Computer Science, London, UK; [5] University of Bath, Department of Mathematical Sciences, London, UK; [6] University of Bath, Department of Mathematical Sciences, London, UK

Abstract

This work presents a modular software integration framework that bridges physics-based PET reconstruction with modern deep learning regularization. While deep learning has shown significant promise in medical imaging, integrating learned priors into established reconstruction pipelines remains a challenge. We address this by developing a direct interface between the DeepInverse library and the Synergistic Image Reconstruction Framework (SIRF), which wraps the Software for Tomographic Image Reconstruction (STIR) engine. This integration enables the direct deployment of learned priors, such as the Deep Residual UNet (DRUNet) and Weakly Convex Ridge Regularizers (WCRR), within accurate physics-based forward models. To demonstrate the framework's flexibility, we integrate and evaluate three reconstruction strategies using learned regularization: PnP-PD3O (WCRR), PnP-SVRG (DRUNet), and PnP-HQS (DRUNet). Performance is validated using a simulated 2D thorax phantom, comparing the proposed framework against Ordered Subsets Maximum A Posteriori One Step Late (OSMAPOSL), corresponding to standard Ordered Subsets Expectation Maximization (OSEM) reconstruction when no prior is applied, and OSMAPOSL with Relative Difference Prior (RDP) baselines. Quantitative results demonstrate improved image fidelity using learned regularization. As a representative example, the PnP-SVRG approach achieved a Peak Signal-to-Noise Ratio (PSNR) of 45.90 dB, compared to 39.52 dB for baseline OSEM, showing improved reconstruction quality using this unified interface. The framework suppresses noise while

preserving structural details. By providing an open-source Python-based bridge, this work lowers the barrier for evaluating state-of-the-art inverse-problem techniques in realistic clinical PET imaging scenarios.

Optimization of CT Reconstruction for Improved Image Quality in Lithium-Ion Battery Modules for Electric Wheelchairs (#1761)

Donghee Kim, Hyung Joo Choi, Chul Hee Min

Yonsei Unuversity, Department of Radiation Convergence Engineering, Wonju, South Korea

This research was supported by the Regional Innovation System & Education(RISE) program through the Gangwon RISE Center, funded by the Ministry of Education(MOE) and the Gangwon State(G.S.), Republic of Korea.(2026-RISE-10-006).

Abstract
Lithium-ion batteries (LIBs) are widely used in electric wheelchairs, and their safety is a critical concern due to the risk of thermal runaway caused by internal defects. In practical applications, batteries are operated as multi-cell modules, and periodic inspection is required as their condition degrades over time. X-ray computed tomography (CT) is widely used for non-destructive testing. However, CT inspection of compact multi-cell modules is challenging since overlapping attenuation from neighboring cells can lead to reconstruction artifacts and reduce defect contrast. In this study, CT reconstruction strategies for multi-cell LIB modules were evaluated using a Geant4-based simulation framework. Projection data were generated under the simulated conditions, and various combinations of projection processing and reconstruction methods were compared. Reconstructed image quality and defect detectability were quantitatively evaluated using the signal-to-noise ratio (SNR), contrast-to-noise ratio (CNR), and detectability index (d′). The results show that the combination of unfiltered projection data, OS-SART reconstruction, and Gaussian smoothing achieved the highest mean d′ across the nine cells. Compared with the

baseline reconstruction, SNR, CNR and d′ improved by 233%, 119% and 117%, suggesting improved defect-to-background separation. These results indicate that reconstruction strategy significantly affects defect detectability, and optimization of reconstruction methods is necessary. In future work, experimental validation will be conducted on a prototype radiography system.

Abstract
PET reconstruction aims to recover the activity distribution from coincidence measurements, while accurate quantitative imaging relies on comprehensive modeling of the physical processes spanning positron annihilation, photon propagation, and detector response. Existing deep learning approaches commonly rely on end-to-end supervision using iterative reconstructions as reference labels, which limits quantitative accuracy and does not explicitly account for the physical degradation mechanisms governing PET measurements. In this work, we propose Wiener Wavelet Net (WieNet), a degradation aware reconstruction framework that models the geometric time of flight probabilistic (GTP) image as a blurred and bias contaminated observation of the underlying activity distribution. A two-stage learnable Wiener filtering strategy is introduced to address TOF induced spatial blurring through frequency domain deconvolution, while a wavelet attention fusion module performs multi energy guided scatter correction by selectively incorporating reliable low frequency information. A 3D denoiser suppresses residual stochastic noise, and an absolute activity calibration module restores the quantitative intensity scale using patient and acquisition parameters. Experiments on clinical and simulated datasets demonstrate that WieNet provides improved scatter compensation and quantitative accuracy compared with fully corrected OSEM and other baseline methods. These findings suggest that degradation aligned reconstruction integrating blur restoration,

scatter correction, and quantitative calibration offers a principled alternative to purely supervised deep learning PET reconstruction.

Abstract
Depth-of-interaction (DOI) information is essential to reduce parallax-related spatial blurring in PET systems using thick scintillation crystals, especially in compact preclinical scanners. We present an image-guided DOI estimation method for a preclinical PET scanner with dual-ended readout, aimed at DOI calibration from both signals. The method follows a superiterative reconstruction strategy. An initial image is reconstructed with a fixed DOI assignment and then used as a spatial prior. Then, from the list-mode file, for each event LOR indicated by a crystal-pair, several DOI candidates are compared for the said crystal pair, generating several possible DOI-LORs. Each candidate LOR is forward-projected onto the previous image, and the value of such projection is used as a compatibility metric. The DOI combination with the highest compatibility is selected to update the DOI-LOR for the given event. To assess consistency, the dual-ended energy ratio was represented as a function of the estimated DOI. The ratio-DOI distributions show a clear depth-dependent trend, indicating that the proposed method provides a DOI response correlated with detector light sharing.

Abstract

In cardiac-gated SPECT studies, the acquired data counts can exhibit significant inter-subject variability. Consequently, the reconstructed images are often processed with post-reconstruction filtering in which the smoothing level needs to be adjusted individually among subjects for optimal noise suppression. In this study, we investigate an operator-interpolation approach to achieve an adaptable level of smoothing with a deep learning (DL) denoising network for processing cardiac-gated images, enabling real-time, patient-specific adjustments without retraining the DL network. We assessed the performance of this approach on a set of 20 clinical gated acquisitions using a DL network pre-trained at two nominal smoothing levels on image data from 862 studies. The results indicate that the proposed approach could achieve nearly identical denoised output images compared to retraining the DL network for a specific target smoothing level, with an average relative mean-squared-error (rMSE) below 0.15% and the structural similarity index measure (SSIM) above 0.982.

LAFOV scanner SAFOV imaging: Sensitivity Restoration by Local Tomography Approach (#2099)

Vladimir Panin[1], Deepak Bharkhada[1], Mael Millardet[2]

[1] Siemens Medical Solutions USA, Molecular Imaging, Knoxville, USA; [2] University of Pennsylvania, Department of Radiology, Philadelphia, USA

The authors would like to thank the Department of Nuclear Medicine at Bern University Hospital's Inselspital, the first site of the Siemens Vision Quadra, for providing patient data.

Abstract

The application of organ-specific imaging on axially long field-of-view (LAFOV) scanners is currently emerging, where an axially shorter CT acquisition defines the target region of imaging. Nevertheless, the PET system naturally acquires additional measurements, where high-polar-angle data contain contributions from both the CT-defined region and the region extending beyond it. Estimation of correction factors, including attenuation and scatter, requires knowledge of the object in the extended region using traditional approaches.

The modern scanner has TOF resolution of a few centimeters, and the TOF local tomography property can be exploited for this task. High-polar-angle PET data, truncated in the TOF domain, can be used, as they contribute to the targeted region. This paper investigates this approach with the goal of faster reconstruction of the target region of interest. Scatter correction is performed using quantitative knowledge of the object obtained from reconstruction of the subset of data for which correction factors are fully known (residual scatter approach). Attenuation can be obtained by a similar approach or by the ML-ACF method using full or TOF-truncated emission data. Alternatively, the attenuation map can be estimated from the full-extent emission data compressed into a single backprojection image using a fast DL method.

Preliminary investigations on the Siemens Vision Quadra show that the sensitivity of the targeted region can be restored with accurate quantification.

Clinically Feasible Deep-Learning–Enabled Dual-Gating Reconstruction for Cardiac PET (#2156)

Kuan-Hao Su, Renato Keshet, Andrew Langholz, Bella Yuzefovich, Sofi Novofastovski, Eli Stern, Sivan Peleg-Cohen, Ariel Lulinsky, Yariv Grobshtein, Gil Kovalski

GE HealthCare, Chicago, USA

Abstract

Cardiac PET imaging is significantly affected by respiratory and cardiac motion, leading to image blurring and reduced quantification accuracy, particularly in motion-sensitive myocardial regions. Although dual-gating techniques can mitigate motion artifacts, their clinical adoption remains limited due to substantial noise amplification and degraded image quality. In this work, we propose a clinically feasible dual-gating reconstruction framework that integrates deep-learning–based denoising with motion-compensated reconstruction to address this fundamental limitation.

The proposed method was evaluated using both XCAT simulations with known ground truth and clinical datasets from 18 patients undergoing Flyrcado and Rubidium (Rb) cardiac PET imaging. A deep-learning denoising model is applied to enhance gated images and improve the robustness of motion estimation. Motion fields are estimated using a symmetric normalization approach and incorporated into a novel multi-pose reconstruction framework, where motion information is directly embedded into forward and backward projections for efficient motion-aware reconstruction.

Simulation results demonstrate accurate recovery of myocardial defects that are blurred or indistinguishable in standard reconstructions without motion correction. Clinical results show improved image sharpness, enhanced myocardial delineation, and preserved count statistics across both tracers, indicating consistent performance under realistic imaging conditions.

By effectively addressing the noise–motion trade-off while maintaining computational efficiency, the proposed framework enables practical clinical implementation of dual-gated cardiac PET imaging. This approach has the potential to improve diagnostic confidence and quantitative accuracy in routine cardiac PET applications.

Abstract

Ultrasound-modulated optical tomography (UOT) is a hybrid biomedical imaging modality that uses a laser beam and ultrasound (US) to reveal optical properties deep within scattering living tissues. It exploits the acousto-optic effect and is based on the detection of photons whose frequency is shifted by the US frequency. Traditionally, focused US waves are used to directly sample the optical image pixel by pixel. To improve the signal-to-noise ratio of the optical image and reduce the acquisition time, US plane waves can be used, resulting in a tomographic problem. However, the finite numerical aperture of the US probe introduces a limited-angle problem, resulting in a loss of lateral resolution. To mitigate this issue, structuration of the plane waves (SW) has been successfully tested for long acquisition times. The objective of the study is to evaluate the performances of Least Squares with Total Variation (LS-TV) tomographic reconstruction in SW UOT for shorter acquisition times, using simulated data with realistic noise levels.

We show first that reducing the number of configurations of the US plane wave structuration from 1353 initially to 41 maintains reconstruction quality for a fixed total acquisition time. Then, we increase gradually the acquisition frame rate from 0.002 Hz initially to 3 Hz. Analysis with adapted regularization parameter reveals a trade-off between frame rate, noise in the reconstructed image, and contrast recovery coefficient (CRC) for an optical absorber mimicking a 1.35 mm radius tumor. Noise increases with frame rate while CRC remains stable below 0.19 Hz and drops significantly above 1.5 Hz.

This study shows for the simulated setup that LS-TV reconstruction enables SW UOT imaging up to a frame rate of 1.5 Hz. It also shows that noise is the primary limiting factor for high-speed UOT rather than sparsity in undersampled SW data.

Abstract

Sparse-view CT reconstruction can reduce radiation dose and acquisition time, but it leads to a severely ill-posed inverse problem. Recent denoiser-based methods such as SNORE provide effective image priors for this setting, yet remain computationally expensive at full resolution. In this work, we propose a multiresolution extension of Prox-SNORE for sparse-view CT. The method solves a sequence of reconstruction problems from coarse to fine resolution levels, using each intermediate solution to initialize the reconstruction at the next finer level. This strategy improves the conditioning of the optimization in the early stages and accelerates convergence at high resolution. Experiments on 30-view CT show that the proposed approach achieves a better time–quality trade-off than standard and annealed Prox-SNORE, while reaching comparable final reconstruction quality. These results suggest that multiresolution optimization is a simple and effective way to make stochastic denoiser-based reconstruction more practical for accelerated CT reconstruction.

Abstract

Positron range introduces a spatially variant, density-dependent blur in positron emission tomography (PET) images of high-energy emitters such as ^{68}Ga and ^{82}Rb, degrading quantification at tissue interfaces. We present a graphics-processing-unit (GPU) implementation of a heterogeneous maximum-likelihood expectation-maximization (MLEM) positron range correction with a joint expectation-maximization/total-variation (EM-TV) update, built on an exact density-weighted forward/adjoint pair derived from a recently published multi-branch range parametrization supporting eight isotopes. The forward operator combines near-field volume integration with far-field Fibonacci-sphere ray traversal of a CT-derived density volume; the adjoint is the matched transpose, and the iterative update conserves total counts exactly. The code corrects a clinical-scale 192x192x335 ^{68}Ga-PSMA volume in 2 minutes (1 iteration, 8 subsets, RTX 3090) and produces visibly sharper structures on a ^{68}Ga mouse acquisition with a preclinical scanner in 45 seconds. The code is publicly available at https://github.com/jlherraiz/PRC_OSEM.

Lutetium-176-Aided Joint Activity and Attenuation Reconstruction in TOF-PET Using Trust-Region Cubic Surrogate Optimization (#2772)

Xin Zhao, Zhijun Zhao, Zhao Wang, Zhaoheng Xie

Peking University, Beijing, China

This work was supported by National Natural Science Foundation of China (62394311) and National Biomedical Imaging Facility Grant.

Abstract
Joint Maximum Likelihood Activity and Attenuation (MLAA) provides a promising CT-less attenuation correction framework but suffers from global scaling ambiguity. Intrinsic Lu-176 background radiation provides patient-specific transmission information to reduce this issue, while introducing a highly nonlinear and ill-conditioned joint likelihood. We propose the Separable Cubic Surrogate with Trust Region (SCS-TR) algorithm, utilizing an analytical Lipschitz constant and a vectorized solver to ensure strictly monotonic convergence and avoid local optima. The reconstruction is initialized with Maximum Likelihood Transmission Reconstruction (MLTR) results. GATE simulations studies demonstrate that SCS-TR effectively recovers clear bone structures and smooth uniform regions without explicit regularization. The proposed method recovered clear bony structures and uniform soft-tissue regions without explicit regularization, and maintained structural fidelity under 20% count statistics.

Organ-based Motion Correction for PET Image Reconstruction using Artificial Intelligence to Segment Organs (#2922)

Eléonore V. Lieffrig[2,1], Vladimir Panin[1], Joshua Schaefferkoetter[1], Deepak Bharkhada[1]

[1] Siemens Medical Solutions USA, Inc., Molecular Imaging, Knoxville, USA; [2] Yale University, New Haven, USA

We are grateful to University hospital at Bern for providing the patient dataset used in this study.

Abstract
Respiratory, cardiac and patient motion during positron emission tomography imaging create artifacts in reconstructed images and can bias their interpretation. In this study, we propose a data-driven, organ-based method to correct motion. Our framework utilizes deep learning-based organ segmentation on no motion corrected images, followed by motion gating derived from centroid of tracer distribution computed within the segmented regions of interest on histo-images. Motion vector fields between the gated images are estimated using the Lucas-Kanade algorithm. Motion is subsequently corrected for in the corresponding gated sinograms and the motion-corrected image is reconstructed from the motion-free sinograms. We demonstrate the effectiveness of our method

by applying it to the liver, enabling accurate estimation and correction of respiratory motion. Qualitative and quantitative results show that our method significantly improves the quality of the reconstructed images compared to no motion correction, and that the organ-specific approach also outperforms motion correction based on motion estimation on the whole abdominal tracer uptake. The average mean and maximum lesion intensities increased by 23.4% and 26.9%, respectively. Combined with better contrast observed on the reconstructed image, these findings suggest that the organ-based approach can recover some true signal that would otherwise be lost due to motion. The proposed framework paves the way for more precise, organ-focused motion correction strategies, enabling the reconstruction of high-quality images tailored to specific anatomical regions.

This research was supported by the National Key R&D Program of China (Grant No. 2022YFC2402000), and the National Natural Science Foundation of China (Grant No. 12375337).

Abstract
In cascaded gamma photon coincidence imaging, coincidence events offer superior spatial localization accuracy. However, their low cascade branching ratio limits detection efficiency compared to single-photon events, resulting in elevated statistical noise and prolonged acquisition times.
Since simultaneously acquired single-photon events also encode the spatial distribution of the radionuclide, we propose a multi-information joint iterative reconstruction algorithm. This method fuses coincidence and single-photon events to construct a joint cost function.

Given the incomplete spatial sampling of single-photon events, linearly integrating these modalities via the MLEM algorithm causes high-count single-photon data to overwhelm the high-resolution coincidence features. This leads to image distortion and edge blurring.
To overcome this, we introduce a Maximum A Posteriori (MAP) estimation framework. Discarding the conventional image-domain spatial smoothing prior, the algorithm utilizes single-photon information simultaneously for direct image reconstruction and projection-domain regularization. Within this framework, a data weighting factor, α, governs the integration of single-photon data in the likelihood term, while a prior penalty factor, β, modulates the anti-distortion penalty.
For ultra-low dose or rapid scanning protocols, increasing α leverages the high detection efficiency of single photons to bolster effective statistical counts, suppress Poisson noise in count-starved coincidence events, and enhance sensitivity. Concurrently, synergizing with β to counteract image distortion yields substantial improvements in image quality and the contrast-to-noise ratio.

Detector-Block-Level Geometric Calibration for Full-Ring Multi-Aperture SPECT Using Analytical Ray-Tracing Simulation (#3028)

Qian Wang, Hongdi Li, Yusheng Li

United Imaging Healthcare North America, Houston, USA

Abstract
Full-ring multi-aperture single-photon emission computed tomography (SPECT) can provide excellent spatial resolution, but geometric misalignments of collimator apertures and detector blocks can substantially degrade image quality. We developed and evaluated a detector-block-level geometric calibration method for full-ring SPECT systems using analytical ray-tracing simulation. The simulated system used the geometry of Alpha-SPECT, consisting of 34 detector modules arranged on a ring with a 40.4-cm radius. Each module contained a 2 (transaxial) × 8 (axial) detector-block array, and each block comprised 40 × 40 CZT crystals with dimensions of 0.5 × 0.5 × 6 mm³. Each module was paired with an 18-mm-thick tungsten collimator containing sixteen 2-mm-diameter pinholes, each focused onto one detector block and separated from the detector surface by 3.1 cm. The proposed calibration estimated source-position offsets and local pinhole and detector-block misplacements by fitting three source-shift parameters and four pose-perturbation parameters for each pinhole–block pair. Simulated projection were generated by ray tracing from a 3 × 3 × 3 grid of 140-keV point sources with 2.5-cm spacing, after applying realistic random perturbations to source positions and system geometry. For each pinhole–block pair, nonlinear least-squares fitting minimized the discrepancy between measured and estimated block projections using independent multistart global optimization followed by two-stage local refinement. Across all detector blocks, the estimated geometric perturbations closely matched the known applied perturbations. Reconstruction of a small Jaszczak phantom using the calibrated geometry showed significantly improved image quality compared with

reconstruction using the perturbed geometry. These results demonstrate that detector-block-level calibration can accurately recover local geometric misplacements and support robust high-resolution full-ring multi-aperture SPECT imaging.

Abstract

Image reconstruction in Positron Emission Tomography (PET) is conventionally performed using Maximum Likelihood Expectation Maximization (MLEM) or Ordered Subsets Expectation Maximization (OSEM). While highly successful clinically, these approaches are limited in their ability to incorporate general regularization functions, particularly non-smooth penalties such as Total Variation (TV). In practice, most clinical reconstruction workflows combine OSEM with post-processing Gaussian filtering, which may lead to oversmoothing or residual noise in low-count acquisitions. In this work, we propose a Chambolle–Pock Primal-Dual Hybrid Gradient (CP-PDHG) framework for PET reconstruction compatible with both sinogram and list-mode representations. The proposed formulation introduces a stacked operator representation enabling simultaneous treatment of complete sinogram and list-mode likelihood terms while naturally incorporating convex regularization functions. We derive closed-form dual updates for the Poisson likelihood and implement Huber-regularized reconstruction as a differentiable

approximation to TV. The method was evaluated on simulated IQ phantom data with count levels ranging from 10^6 to 10^8 detected coincidences and on clinical long axial field-of-view (LAFOV) PET acquisitions acquired on a Siemens Biograph Vision Quadra system. In noiseless simulations, CP-PDHG achieved convergence rates comparable to MLEM, while in low-count scenarios it demonstrated substantially improved noise behavior. Regularized CP-PDHG consistently outperformed MLEM with Gaussian post-filtering in both simulated and clinical low-count reconstructions, showing improved lesion conspicuity and reduced noise propagation.

Investigation of hybrid CT-free attenuation correction framework with TOF-MLAA and deep learning (#1209)

Yuya Onishi, Kibo Ote, Takashi Isobe

Hamamatsu Photonics K.K., Central Research Laboratory, Hamamatsu, Japan

This work was partially supported by the JSPS KAKENHI (grant number: JP24K10802).

Abstract
Positron emission tomography (PET) attenuation correction (AC) is essential for achieving quantitative accuracy and is conventionally performed using computed tomography (CT). However, CT-based AC introduces challenges such as image misregistration and additional radiation exposure. Although deep learning-based CT-free AC methods have shown promising performance, concerns remain regarding the reliability and physical consistency of purely data-driven attenuation estimates. In this study, we investigate a hybrid CT-free AC framework that combines deep learning-based attenuation estimation with maximum likelihood reconstruction of attenuation and activity using time-of-flight information (TOF-MLAA). As an initial step toward this integration, we focus on evaluating the TOF-MLAA performance for attenuation-map reconstruction using emission data alone. Monte Carlo simulation was conducted using a realistic digital brain phantom and a brain-dedicated PET scanner geometry. The results demonstrate that TOF-MLAA can reconstruct attenuation maps with anatomically plausible structures and physically meaningful spatial distributions, despite residual noise and quantitative inaccuracies. As a next step, tracer-agnostic deep learning-derived attenuation estimates will be incorporated into the TOF-MLAA framework.

This integration is expected to improve the stability and quantitative performance of attenuation reconstruction while enhancing the reliability and physical consistency of deep learning-generated attenuation maps.

Crystal-Wise Dead-Time Correction: Application to VRAIN (#1619)

Hideaki Tashima, Go Akamatsu, Yuma Iwao, Taiga Yamaya

National Institutes for Quantum Science and Technology, Institute for Quantum Medical Science, Chiba, Japan

Abstract
Dead-time correction is important for quantitative PET imaging; however, typical methods are approximate, as global dead-time correction is applied using system-level count-rate information. Even with more refined methods, such as block-wise correction, limitations remain. On the other hand, one-to-one coupled detectors, which provide independent signal readout for each crystal, may exhibit crystal-dependent variations in count rate and dead-time behavior. In this study, therefore, we developed a crystal-wise dead-time correction method for the brain-dedicated PET system VRAIN, in which each scintillator crystal is coupled to an individual SiPM. Singles count rates for each crystal were calculated from singles event data acquired during measurement of an ^{18}F-filled phantom over a wide range of radioactivity levels and the rates were used to estimate dead time. Dead-time factors representing sensitivity reduction due to count loss were modeled using both non-paralyzable and paralyzable models. The factors were estimated for arbitrary acquisition time frames and incorporated into the forward projection model of a list-mode OSEM reconstruction algorithm. To evaluate the proposed method, pool phantom measurements were performed and compared with a detector-wise correction method. The proposed method showed improved linearity with radioactivity compared with the detector-wise approach. Comparable performance was observed between the two dead-time models, while the non-paralyzable model showed slightly better linearity. These results demonstrate the feasibility of crystal-wise dead-time correction for improving quantitative accuracy in brain PET systems with one-to-one coupled detectors.

Abstract

The easyPET.3D system is a preclinical positron emission tomography (PET) scanner featuring a non-conventional acquisition geometry based on the dual-rotation of two opposing detector modules, combining a fan rotation for angular sampling and an axial rotation for volumetric coverage. Its performance was previously evaluated following the NEMA NU 4-2008 standard, demonstrating consistent spatial resolution across the field-of-view. However, such assessment relies on filtered back projection, an analytical reconstruction method that may not accurately represent the performance of systems with unconventional geometries, where its application can be challenging, thereby limiting the direct applicability of the standard protocol. In this work, the easyPET.3D spatial resolution was further investigated using a micro-Derenzo phantom and iterative reconstruction (LM-MRP), enabling a more realistic and application-oriented evaluation. A quantitative metric based on the smallest resolvable rod diameter was introduced to formalize the commonly adopted smallest resolvable rod criterion and provide a simple and reproducible indicator under practical imaging conditions. The analysis was performed for the three predefined acquisition modes of the system (fast, medium, slow), previously established based on optimized operating parameters. These modes differ in axial rotation step angle and acquisition time, reflecting distinct sampling conditions while preserving the same hardware configuration. This work explores a more application-oriented approach for assessing spatial resolution in preclinical PET systems with non-conventional geometries.

PET Spatial Resolution Repeatability and Reproducibility Following the NEMA NU 2 Standard (#2134)

Benjamin A. Spencer[1], Yifan Wu[2], Yun Dong[2], Lorenzo Nardo[1], Brahim Mehadji[1]

[1] UC Davis Health, Radiology, Sacramento, USA; [2] United Imaging Healthcare, Shanghai, China

Abstract

The NEMA NU 2 protocol provides the standard for positron emission tomography (PET) spatial resolution evaluation and benchmarking, yet its reproducibility and repeatability have not been rigorously evaluated for modern PET systems. In this study, we investigated the variability of NEMA spatial resolution measurements using the uEXPLORER total-body PET scanner under controlled experimental conditions. A total of 195 point source measurements were acquired to determine an estimate of NEMA spatial resolution uncertainty along with the effects of capillary size, activity concentration, and acquired counts. Spatial resolution was computed following the NEMA standard using in-house code and a vendor provided tool for filtered back projection reconstruction. Despite controlled experimental conditions, statistically significant differences were observed in 16 of 86 comparisons indicating limited reproducibility across experiments. From our measurements we determined that a single NEMA spatial resolution measurement exhibits an uncertainty of approximately 0.2 mm (≈5%), improving to 0.1 mm (≈3%) with repeated acquisitions. There was no observed impact to spatial resolution from capillary size (0.3–1.0 mm) or total counts acquired, while a potential dependence on activity concentration was identified but requires further validation. These findings highlight a discrepancy between reported precision in the literature and practical measurement variability. We recommend incorporating repeated measurements and reporting uncertainty to ensure meaningful benchmarking. Revisions to the NEMA protocol may be necessary to better reflect the performance of modern PET systems

The project "*Next generation BrainPET scanner for 7T MRI*" was supported by the Helmholtz Validation Fund No. 0051 and the Innovation Go funding of the Forschungszentrum Jülich GmbH for the project “BrainPET-7T”.

Abstract

In PET, the large dynamic range of activity in the scanner field-of-view (FOV) represents a significant challenge in accurately detecting and quantifying all incoming photons and coincidences. Block pileup and deadtime, well-known effects that increase non-linearly with the activity exposure, are unavoidable for all types of detector hardware. Thus, the observed global sensitivity at the block-level, as well as the detection efficiency at the crystal-pixel level, can be strongly impacted. The adequate characterization and correction of these sources of bias is imperative to obtain artifact-free quantitative images from the reconstruction process.In this work, we characterize such activity dependencies for our Jülich BrainPET-7T insert, which is designed as hybrid PET/MR system for advanced neuroscience applications. The new BrainPET-7T insert comprises 120 detector blocks with a three-staggered-layer design using a 12x12 matrix of digital silicon photomultipliers (dSiPM) from Philips DPC to detect light. A ^{11}C-decay experiment using a homogeneously filled cylinder was performed to quantify changes in terms of individual block deadtime and crystal efficiency maps as a function of the FOV activity. Assuming the low activity regime is (approx.) unbiased allows quantification of deviations with respect to higher activities by extrapolation of ground truth values. A block deadtime of 11-13% was found for a total FOV activity of 195 MBq. Furthermore, the crystal efficiency patterns showed a continuous evolution over the covered activity range, necessitating compensation in terms of dynamic adjustment of the scanner normalization to prevent streak artifacts in reconstructed images in the high activity regime.

Abstract

In this work we apply the fully automated motion correction algorithm using open source Software for Tomographic Image Reconstruction (STIR) with automated motion detection for [^{18}F]-Flutemetamol ([^{18}F]-FMM) tracer for β-amyloid accumulation in the brain cortex region. The visual results show significant improvement in contrast in the Pons and Cerebellum region with decrease blurring at the edges around the cortex region of the brain. The quantitative results shows statistically significant agreement of centiloid, a metric for early diagnosis Alzheimers' disease, between the motion corrected [^{18}F]FMM tracer and the noisy longest frame without detectable motion using the single sided Wilcoxon test at 5% compared to no motion correction.

Abstract
Spontaneous patient motion degrades image quality and compromises quantitative accuracy in brain PET imaging. In this work, we present and evaluate three data-driven approaches for rotational motion detection using list-mode PET data: a point-cloud-based principal component analysis (PCA) method operating on LOR midpoint coordinates, a PCA method applied to backprojected images, and a convolutional neural network (CNN)-based approach. Controlled measurements were performed using an anthropomorphic head phantom on a custom holder allowing isolated single-plane rotations, with ground truth determined via MRI at each position. The PCA-based methods achieved an angular precision of 1-3 degrees, with the backprojection-based implementation additionally reducing signal cross-talk between projection planes. A full comparison of all three methods will be presented at the conference.

Abstract
Positron Emission Tomography (PET) detector systems are continuously being developed and optimized to enhance sensitivity and spatial resolution. Standards, such as those defined by the National Electrical

Manufacturers Association (NEMA), are essential for reliable performance assessment. However, little has changed between the first (NU 2-1994) and the latest (NU 2-2024) NEMA standard on spatial resolution assessment of PET scanners. Also, the small animal PET scanner standard (NU 4) has not been updated since 2008. Reconstructing point sources with outdated filtered back-projection remains mandatory. Although Maximum Likelihood Expectation Maximization (MLEM) algorithms are favored for achieving higher resolution and lower noise, their use for spatial resolution assessment is discouraged, since reconstructed point sources can become arbitrarily small with many iterations [1]. In this work, we propose a protocol for rigorous and accurate estimation of the spatial resolution of MLEM-reconstructed images. Our method relies on the Derenzo phantom [2], yet, any hot-rod phantom may be used. Spatial resolution is assessed in two steps. First, Modulation Transfer Function (MTF) values are extracted at spatial frequencies defined by the rod sizes. Then, a parametric MTF model is fitted to derive the resolution from the associated Point Spread Function (PSF). We show that this method converges, removing the dependence on the number of iterations. We further demonstrate that it yields spatial resolution values consistent with theoretical expectations. Therefore, we recommend updating the upcoming NEMA NU 2 and NU 4 standards to reflect established iterative reconstruction practices and enable a robust assessment of spatial resolution across PET systems.

Abstract
In this work, random and scatter corrections were developed for N-PET, a dedicated brain PET system, using the correction framework supported by CASToR. Each detector module contains dual-layer LYSO scintillator arrays with four DOI encoding bins. Random coincidences were estimated using the delayed window method, while scatter coincidences were estimated using a GATE Monte Carlo simulation model. Both random and scatter

estimates were incorporated as additive terms in the iterative reconstruction model. To improve the statistical stability of sparse LOR-level estimates, each 2×2 neighboring crystal array was grouped as one block. For each block-pair, the random and scatter counts from all corresponding crystal-level LORs were summed and evenly redistributed to the LORs within the same block-pair.
Random correction was evaluated experimentally with an image quality phantom containing three hot spheres with diameters of 13 mm, 22 mm, and 37 mm. The results showed that random correction reduced background noise outside the phantom, and normalization and attenuation correction further improved image uniformity and hot sphere visibility. Scatter correction was preliminarily evaluated using GATE simulation. The proposed method increased the CRC of the 13 mm hot sphere from 0.49 to 0.60, which was comparable to the scatter-free reconstruction result of 0.59. These results show that the proposed list-mode-based random and scatter correction method improves the reconstructed image quality of the N-PET system. Future work will validate the scatter correction with experimental data and further optimize the accuracy of both corrections.

Abstract
Accurate patient attenuation maps (μ-maps) are essential for precise PET quantification. In this study, we compared four methods for generating brain μ-maps in TOF PET/MRI scans and evaluated their impact on reconstructed PET images. We analyzed MRI segmentation, MLAA-based attenuation correction, and two deep learning (DL) approaches: convolutional neural networks (CNN) and denoising diffusion probabilistic models (DM). Two clinical studies utilizing [^{18}F]-FDG and [^{18}F]FE-PE2I tracers on a Siemens BIOGRAPH One PET/MRI (Siemens Healthineers) were examined. The MR-based technique occasionally misclassified skull bone and paranasal sinuses as soft tissue. Both DL networks produced reasonable μ-maps for [^{18}F]-FDG but struggled with the [^{18}F]FE-PE2I data, which was absent from the training set. While MLAA-based μ-maps assisted in recovering missed bone and sinuses, they were more susceptible to noise. For [^{18}F]-FDG, μ-map variations did not cause major PET quantification differences, though MLAA showed a slight overcorrection. Conversely, for [^{18}F]FE-PE2I, CNN-based attenuation led to an activity underestimation of up to 10% in the striatum. This study highlights the importance of μ-map selection, and future work will utilize PET/CT for a systematic "ground truth" comparison.

Abstract

Quantitative PET requires attenuation correction (AC) to compensate for the loss of annihilation photons due to absorption and scattering within the patient's body [1]. The current clinical gold standard is CT, but it increases radiation dose, hardware costs, and registration complexity [2]. These limitations motivate the exploration of CT-less AC approaches in PET imaging [3]. One such method is Detector Scattered Attenuation Correction (DSAC), which uses detector-scattered photons to estimate the attenuation map from the PET data itself [4]. In DSAC, detector-scattered (DS) coincidences are used. These coincidences define lines of response (LORs) in which a gamma ray undergoes Compton scattering in one detector module and then deposits its remaining energy in another detector module after passing through the patient. As these photons pass through the phantom, attenuation information is encoded through photoelectric absorption and scattering. In this comparative study, we use GATE simulations [5] with two different materials, plastic and LYSO, to estimate attenuation maps via DSAC. The results show that plastic scintillator based JPET Scanner [6,7] yield a significantly higher DS-coincidence fraction (47%) than LYSO (1.2%), representing a 6.3-fold increase in useful statistics despite the lower raw registration efficiency of plastic. Single Slice Rebinning (SSRB) reconstructions show lower absolute error, better uniformity, and reduced cupping for plastic, while the phantom remains visible for LYSO despite its lower DS statistics. Our study concludes that DSAC is feasible for PET imaging with both scintillator types, with plastic offering stronger DS statistics and improved preliminary quantitative metrics

Abstract

Accurate randoms correction in PET is typically achieved via delayed-window (DW) or singles-product (SP) methods, both requiring dedicated hardware unavailable on many research PET systems. We present Non-imaging Pairs Random Estimation (NPR), a calibration-free estimator that uses detector pairs whose lines of response (LORs) lie outside the reconstruction field of view (FOV) as a random-coincidence baseline. Per-pair randoms are estimated in three closed-form steps from prompt list mode data alone. Validated against GATE Monte Carlo ground truth on data acquired across 38 simulations spanning random fractions 9–99%, NPR achieves per-pair MAE = 0.45%, matching DW (0.50%) and SP (0.35%) for spatially distributed sources. Under a 5×-singles-asymmetry hot-sphere stress test, NPR retains 1.96% MAE (matching DW, which is also robust) while SP fails by +230%/-33%. A 20-pair FPGA configuration supporting NPR45 (neighbor pairs only, MAE = 0.50%) is demonstrated on R-PET with an ^{18}F capillary phantom.

An Exponential Total Variation Functional to Replace the Total Variation Norm (#1061)

Gengsheng L. Zeng[1], Ya Li[2]

[1] Utah Valley University, Computer Science, Orem, USA; [2] Utah Valley University, Mathematics, Orem, USA

This work was supported in part by the National Institutes of Health under Grant R15EB024283

Abstract

In iterative image restoration, the total variation (TV) norm is the most common regulator to control noise and enforce sharp edges in the images. This paper proposes an exponential version of the TV norm. This exponential version of the TV norm behaves similar to the L_p norm for $0 < p < 1$ and it promotes sharp image edges better than the TV norm. This exponential TV is easy to implement. We use computer simulations to compare the effectiveness of preserving sharp edges by the TV regulator and by the exponential version. The image restoration task is image denoising. The exponential regulator is demonstrated as more effective in obtaining piecewise-constant images than the popular TV regulator.

Abstract

Walk-through positron emission tomography (WT-PET) is an emerging upright imaging geometry based on two vertically opposing flat detector panels. Although this design may improve patient comfort and acquisition efficiency, respiratory motion remains a major source of image degradation. This study evaluates respiratory motion correction strategies for WT-PET using XCAT anthropomorphic simulations. A 30s acquisition was simulated in a WT-PET geometry and reconstructed using an in-house MLEM-based algorithm. Data-driven amplitude- and phase-based respiratory gating were followed by non-rigid motion correction using Advanced Normalization Tools (ANTs) and Fast Algorithms for Motion Correction (FALCON). Overlapping-frame reconstruction using 0.9375s windows shifted every 0.3125s was also evaluated to assess the effect of temporal smoothing. Performance was quantified against a motion-free reference using normalized root mean square error (NRMSE), diaphragm edge width, and line profile analysis. ANTs phase-based 4-gate correction achieved the best performance, reducing NRMSE from 64% to 6% and restoring the diaphragm edge width to the motion-free reference level (25.10 mm vs. 25.79 mm). FALCON phase-based 4-gate correction reduced NRMSE to 12% but showed limited recovery of diaphragm sharpness, with an edge width of 28.40 mm compared with 28.62 mm for no motion correction. Overlapping-frame ANTs correction reduced NRMSE to 15% and yielded an intermediate edge width of 27.13 mm, although line profiles indicated residual local displacement and smoothing. These findings show that data-driven respiratory gating combined with deformable registration can substantially improve image quality in upright WT-PET.

Abstract

Modern Positron Emission Tomography (PET) scanners are increasingly complex, incorporating a large number of modular detectors that require meticulous synchronization. Precise calibration of detector parameters, such as energy response, depth-of-interaction (DOI), and time-alignment, is essential to maintain image quality. This work presents a robust multi-parametric correction pipeline applied to two LYSO based, DOI capable PET scanners: a preclinical (12 cm transaxial FOV) device and a extended Field of View clinical geometry (23 cm transaxial FOV) scanner, targeting four primary sources of systematic degradation: crystal-by-crystal energy centroid offsets, individual crystal gain non-uniformities, time alignment, and DOI-dependent energy and time variations. Calibration data were acquired from reference point sources and specialized phantoms to ensure statistical reliability. The timing alignment pipeline, which iterates recursively over crystal- and detector-level centroids, improved the Coincidence Time Resolution (CTR) by 50% through the effective mitigation of electronic offsets and time-walk effects. Furthermore, DOI-dependent energy corrections linearized the crystal response, improving energy resolution from 25.0% to 12.6% FWHM. These results demonstrate that a modular multi-parametric calibration framework significantly optimizes timing and energy performance across heterogeneous PET architectures, providing a scalable solution for high-sensitivity molecular imaging.

Abstract
We investigated whether a positron emission tomography-derived latent biomarker can serve as a compact prognostic signal after longitudinal modeling. The study used 3,458 scans from 1,624 participants in the Alzheimer's Disease Neuroimaging Initiative. A Bayesian mixed-effects model was fitted to the biomarker trajectory and evaluated in two practical settings: forecasting future visits for previously observed subjects and estimating short-term dementia risk from predicted biomarker values. For subjects already observed during training, future visits were predicted with a mean root mean squared error of 0.298 and a mean absolute error of 0.250. For entirely new subjects, a change-from-baseline formulation reduced prediction error to a mean root mean squared error of 0.217 and a mean absolute error of 0.171 after an initial scan. A training-only logistic calibration applied to held-out predictions reached an area under the receiver operating characteristic curve of 0.826 for future dementia risk estimation. These results suggest that the latent biomarker can move beyond representation learning and support short-term longitudinal forecasting and clinically interpretable risk stratification.

Abstract

Data augmentation techniques applied in state-of-the-art image reconstruction with deep learning in the positron emission tomography (PET) modality are performed in the reconstructed image domain and subsequently forward-projected to the sinogram domain. In this work, we present a method for applying affine rotation and scaling transformations to sinogram images obtained from a series of simulations in GATE. The proposed algorithms were validated on 100 2D sinogram slices from Nema-like and Jaczack-like phantoms. The preliminary results from this study indicate that the proposed methods are visually indistinguishable from those obtained by applying the transformation in the image domain and then forward projecting to the sinogram domain. The quantitative evaluation was performed using the metrics Zero Mean Normalized Cross-Correlation (ZNCC), which yielded mean values over 0.95, and the Gradient Normalized Cross-Correlation (GNCC), which yielded mean values over 0.66, for both the rotation and scaling transformations. These preliminary results show that the implemented algorithms could be considered the first of their kind, designed to tackle data augmentation directly in the sinogram domain.

Abstract
Multiplexed positron emission tomography (mPET) is an emerging method that enables two or more tracer distributions to be separated from data acquired in one PET scan. The technique requires high detection efficiency for triple coincidences resulting from a prompt-gamma and two annihilation photons emitted from a positron+prompt gamma emitter. In this study, we focus on multi-hit events occurring within the same coincidence timing window inside the same detector, which are typically discarded as multi-photon hits or inter-crystal scatter (ICS). We propose a recovery method for both annihilation and prompt-gamma events from these multi-hit events, thereby improving the detection sensitivity for triple coincidences. We first generated a new charge-to-digital converter (QDC)–based energy window derived from single-hit 511 keV events for each crystal. This crystal-specific window was then applied to each hit in multi-hit events, and then each hit was classified as either an ICS, annihilation photon, or prompt-gamma event. Evaluation with a ^{22}Na point source placed at the center of the scanner showed increases of 3.5% in annihilation photon singles, 10.8% in prompt-gamma singles, 1.1% in double coincidences, and 9.1% in triple coincidences. These results indicate that the proposed method recovers useful events and enhances triple-coincidence sensitivity for mPET.

Abstract
We present the Hyperion DAQ (data acquisition platform), a versatile MRI-compatible infrastructure for PET detector data acquisition. It combines firmware on a sensor-tile FPGA and a mainboard FPGA with a software stack that splits between a Data Acquisition and Processing System (DAPS) host — receiving and processing the

ASIC data over a 10 Gig Ethernet downstream link — and a separate control computer that coordinates the platform components. The firmware handles ASIC configuration, capture and per-packet annotation; the higher-level calibration routines run in software. We have integrated the PETsys TOFPET2 ASIC as the first front-end digitization chip and built an end-to-end calibration suite on top of the platform: breakdown determination via bias sweeps, signal-level and threshold calibration via discriminator sweeps, a charge-to-digital converter (QDC) linearization sampled by on-tile test pulses and stored as a per-bin lookup table, and a time-to-digital converter (TDC) calibration driven by the natural random trigger stream from a 511 keV source. All four routines run in-system on the assembled scanner. We further report on the ASIC's test-pulse insensitivity window, showing that its position depends on the end phase of the test pulse rather than its start phase — a finding relevant to anyone calibrating the TDC with a test-pulse-based code-density method. On a Visor Max detector pair (8×8 6 mm Broadcom SiPMs read out by a single TOFPET2 ASIC, 64 LYSO crystals per tile), three ^{22}Na sources, 5 V over-voltage and 17°C cooling, we measure an energy resolution of 10.7 % FWHM at 511 keV and a coincidence time resolution of 248 ps FWHM. An end-to-end evaluation of the data-rate handling of the firmware and software acquisition chain will be presented at the conference. The platform is being prepared for the next generation of Hyperion-based PET/MRI scanners.

Abstract

Accurate lesion-level dosimetry is essential for evaluating therapeutic response in radiopharmaceutical therapy; however, its reliability in SPECT/CT imaging is limited by partial volume effects, which can significantly underestimate activity concentration in small or heterogeneous lesions. These limitations become particularly important when comparing radionuclides with different emission characteristics, such as the widely used ^{177}Lu and the emerging ^{161}Tb, which emits additional low-energy electrons that may enhance microscopic dose deposition. In

this study, we performed a lesion-level dosimetric analysis of ^{161}Tb-FAPI and ^{177}Lu-FAPI using a Monte Carlo simulation framework based on patient-specific SPECT/CT data. Two iterative partial volume correction methods, Richardson–Lucy and reblurred Van Cittert, were applied to assess their impact on absorbed dose estimation. Lesions were segmented on SPECT images, and voxel-wise dose maps were generated using GATE simulations, followed by lesion-level dose aggregation. Relative dose differences were calculated by comparing corrected and non-corrected images. Results show that partial volume correction significantly affects lesion dosimetry for ^{177}Lu-FAPI, with dose increases reaching approximately 30.6% in bone metastases and 23.2% in liver lesions, while changes in corresponding normal tissues remained minimal. In contrast, ^{161}Tb-FAPI exhibited more stable behavior, with lesion-level variations generally limited to below 10% and moderate reductions observed in lung lesions (≈ −15%). Both correction methods produced consistent trends, with slightly lower magnitude changes for the reblurred Van Cittert approach. Overall, these findings indicate that lesion-level dose estimation for ^{177}Lu is highly sensitive to image correction, whereas ^{161}Tb provides more robust dosimetric estimates.

A Quality Control Framework for Deep Learning-based Attenuation Map Synthesis in PET (#2579)

Zhen Ji[1], Yue Li[2], Chenyao Jiang[2], Chen Sun[2], Xiong Wang[1], Yihuan Lu[2]

[1] ShanghaiTech University, School of Information Science and Technology, Shanghai, China; [2] Shanghai United Imaging Healthcare Co., LTD, Molecular Imaging Business Unit, Shanghai, China

Abstract
Deep learning-based attenuation correction (DL-AC) offers potential advantages over conventional CT-based attenuation correction (CT-AC) in PET imaging, including avoidance of additional radiation exposure and reduced susceptibility to PET–CT misalignment. However, in DL-AC application scenarios, when CT-derived attenuation maps (CT-μ) are unavailable as reference images, quality control (QC) of deep learning-derived attenuation maps (DL-μ) often relies on manual inspection. To address this limitation, we propose a patch-level 3D convolutional neural network (3D CNN) framework for automated anomaly detection and localization in DL-μ without requiring CT during inference. During training, CT-μ was used to assist patch-level annotation of DL-μ, and artifact-free CT-μ patches without observer-identified abnormalities were incorporated as normal samples to help the model learn normal attenuation patterns. During inference, only DL-μ was used, and sliding-window prediction was used to aggregate patch-level anomaly probabilities into a voxel-wise anomaly probability map. On the validation set (51 cases), the framework yielded patch-level performance with an AUC of 0.9984, an F1-score of 0.9802, a sensitivity

of 97.06%, and a specificity of 98.86%. These results suggest that the proposed framework can provide spatial cues for DL-μ, potentially supporting efficient evaluation and reducing reliance on manual QC inspection.

Generating synthetic PET/CT scans with latent diffusion models (#2763)

Kevin H. Leung[1], Esther Mena[2], Peter L. Choyke[2], Sangeeta Ray[1], Yong Du[1]

[1] Johns Hopkins University School of Medicine, Russell H. Morgan Department of Radiology and Radiological Science, Baltimore, USA; [2] National Cancer Institute, Center for Cancer Research, Bethesda, USA

Abstract
Artificial intelligence approaches require training on large amounts of data to achieve acceptable levels of performance as well as generalizability. However, there is a lack of available annotated datasets for nuclear medicine imaging modalities as they are a relatively low-volume clinical modality, especially when compared to other anatomical imaging modalities, such as CT and MRI. We aim to leverage a deep generative modeling approach based on latent diffusion models to generate synthetic PET/CT images to address this issue. ^{18}F-FDG PET/CT and ^{18}F-DCFPyL PET/CT scans of 668 patients with various types of cancer, including lung cancer, melanoma, lymphoma, and prostate cancer were used to train a latent diffusion model. The data were randomly partitioned into training and test sets using a 90%/10% split. A hierarchical, latent diffusion modeling approach was trained in multiple stages. A patch volume autoencoder was trained to learn a discrete latent representation of local image volume patches using a vector quantized-variational autoencoder. A diffusion model was then trained to generate image volumes sampled from random noise in the latent space. Image quality metrics, including peak signal to noise ratio (PSNR) and mean absolute error (MAE), were evaluated across the training and test sets. On the training set, the approach yielded PSNR values of 40.85 ± 5.50 dB and 36.77 ± 5.30 dB and MAE values of 0.015 ± 0.01 and 0.021 ± 0.011 between the generated and original PET and CT image volumes, respectively. On the test set, the approach yielded PSNR values of 40.00 ± 6.19 dB and 35.48 ± 5.75 dB and MAE values of 0.017 ± 0.012 and 0.030 ± 0.075 between the generated and original PET and CT scans, respectively. The approach achieved relatively high PSNR and low MAE values, respectively, indicating that the approach generated high fidelity PET and CT images. The present study demonstrated a proof of concept for generating realistic PET/CT volumetric scans.

Abstract

Quantum-inspired denoising is employed for clinical PET/CT, PET/MR, and SPECT imaging by treating images analogous to disordered materials and analyzing the eigenfunctions of an associated Hamiltonian. Quantum localization is quantified by the participation ratio, enabling filtering of non-localized, high-participation modes that dominate the mid-frequency range and are associated with diffusive noise. By suppressing these modes and reconstructing from the remaining localized modes, noise is reduced without training data or manual regularization. The framework is applied to 46 multi-vendor, multi-tracer patient datasets from Massachusetts General Brigham to characterize scanner-dependent noise structure and its impact on image appearance. Across the cohort, quantum-inspired filtering yields consistent decreases in blind image quality scores (PIQE and BRISQUE) together with increases in entropy and Laplacian variance, indicating lower perceived noise and enhanced structural detail in the denoised clinical images.

Abstract
Patient motion remains a common challenge in dynamic cardiac positron emission tomography (PET), as it degrades image quality and complicates reliable evaluation of motion correction methods. Realistic motion simulation requires motion models that capture the variability observed in clinical data, but this remains difficult when simulations rely on only a limited set of motion patterns. In this work, we propose a data driven framework for motion model selection and simulation in dynamic cardiac PET. We characterize motion trajectories using physically interpretable features and analyze them using clustering and trajectory similarity based on dynamic time warping to identify a compact set of representative motion models. These models are integrated with patient-specific motion scaling for frame-wise simulation of motion-corrupted PET data. The proposed framework produces stable normalized error levels across 1308 patient–model evaluations while using only a small number of representative motion models. The results suggest that the selected models effectively capture dominant motion behaviors observed in the dataset and enable realistic PET motion simulation.

Abstract
Patient head motion during positron emission tomography (PET) brain imaging degrades system spatial resolution and quantitative accuracy; even sub-millimeter displacements can blur fine structures in highresolution systems. We present the validation of an OptiTrack PrimeX 41 fourcamera near-infrared stereocamera system for use with a novel γβ⁺ brain-imaging prototype targeting ≤0.200mm spatial accuracy and ≤250ms temporal synchronization with list-mode data acquisition. System calibration achieved a mean residual of 0.075mm, below the manufacturer's 0.1

mm specification. Tracking accuracy was characterized over 360,000 Euclidean-distance measurements using a Capintec brain phantom displaced by Zaber precision stages (repeatability ≤0.050mm) as ground truth, yielding RMSE of 0.018–0.038mm and maximum outliers ≤0.135mm across three orthogonal directions that were at least 5× better than the 0.200mm target. Three temporal synchronization strategies were evaluated; a network-based UDP broadcast produced a correctable 17.2±2.4ms transmission delay, yielding a combined synchronization uncertainty of 57ms versus the 250ms requirement. Performance was maintained in a clinically realistic configuration with a mock 40-cm imaging bore and supine patient positioning.

Abstract

Tracer kinetic modeling using the two-tissue (2T) compartment model remains challenging in dynamic SPECT imaging, particularly under realistic noise conditions. In this study, we propose a noise-robust Bayesian parameter estimation method that incorporates physiological prior information for the 2T model in dynamic SPECT imaging. To validate the proposed method, we conducted both simulation study and dynamic ^{99m}Tc-4BOH clinical study. The proposed method was compared with the conventional nonlinear least-squares (NLS) method. In the simulation study, the proposed method yielded lower relative bias in the estimated kinetic parameters (K_1, k_2, k_3, and k_4) than the NLS method under both low and high noise conditions. In the clinical ^{99m}Tc-4BOH study, K_1 estimated using the proposed method demonstrated significantly stronger agreement and lower relative bias with respect to head-to-head ^{13}N-NH_3 PET myocardial blood flow (MBF), which was used as the reference standard, than the NLS method. In conclusion, the proposed method substantially improved the accuracy and precision of parameter estimation for the 2T model compared with the NLS method.

Abstract

We propose a kinetic-consistent conditional flow matching framework for dynamic *[11C* raclopride PET SRTM parametric imaging. Conventional indirect SRTM fitting is vulnerable to frame-wise count noise, causing unstable voxel-wise *R1* , *k2* , and *BPND* maps. Using 105 scans from 35 subjects, count-reduced datasets were generated at 50%, 25%, and 10% of the original counts. The model refines reduced-count indirect SRTM estimates toward full-count SRTM pseudo-reference maps using kinetic consistency, count/noise conditioning, and physiological constraints, reducing *BPND* deviation, high-percentile errors, and kinetic-parameter disagreement compared with indirect SRTM and denoising and regularization-based baselines

Treatment Monitoring System for Proton Therapy Based on Beam Range Measurement (#1067)

SeHyun Jang[1], Jaeho Cho[1], Goeun Lee[1], Taehyeon Eom[1], Junyoung Lee[1], Jong Hwi Jeong[2], Sung Hun Kim[2], Sungkoo Cho[3], Kwanghyun Jo[3], Chan Hyeong Kim[1]

[1] Hanyang University, Nuclear Engineering, Seoul, South Korea; [2] National Cancer Center, Proton Therapy Center, Goyang, South Korea; [3] Samsung Medical Center, Department of Radiation Oncology, Seoul, South Korea

Abstract

In proton therapy, range uncertainties can result in insufficient dose delivery to the tumor or unintended dose delivery to organs at risk (OARs). To address this, several range verification methods have been investigated, and prompt gamma imaging is considered a promising method due to the strong correlation between the dose profile and prompt gamma distribution at the distal dose fall-off location. Based on prompt gamma imaging, a treatment monitoring system was developed to measure the in vivo beam range and detect range shifts during the treatment. The developed system consists of a 72-slit parallel collimator, 144 CsI(Tl) scintillation detectors, a dedicated field-programmable gate array (FPGA)-based data acquisition (DAQ) system, and a dedicated program with a graphical user interface (GUI). The DAQ system calculates pulse height and timing of each signal from 144 detectors. The dedicated program reconstructs 1D prompt gamma distribution using pulse data and determines the beam range of each spot using a dedicated range estimation algorithm [1]. The system's performance was evaluated using a clinical proton beam prescribed to deliver 0.5 Gy to a spherical clinical target volume (CTV) with 50 mm diameter in a homogeneous PMMA phantom. To evaluate range shift detection performance, range shifts were induced at both the global range shift (1–10 mm) and local range shift (5 and 10 mm) conditions. At the same time, the computation time for range deviation analysis was evaluated. The system detected global range shifts with an accuracy of 1 mm and identified the presence and location of local range shifts exceeding 5 mm. Furthermore, the time required for range deviation analysis per layer was found much shorter than energy layer switching time. These results demonstrate the system can verify the in vivo beam range during treatment in clinical practice.

Abstract

Proton range verification (PRV) in proton therapy is an outstanding clinical need. Prompt-gammas (PG) emitted along the proton track constitute a strong signal to determine the Bragg Peak position. However, the high energy of PGs (1-7 MeV), the high particle flux and the presence of significant background radiation make prompt-gamma imaging (PGI) challenging.

We report on the development of pure Cherenkov pixelated detectors for PRV. The detector consisted of an 8×8 pixelated PbF2 crystal array coupled to an 8×8 S14161-3050HS-08 SiPM array from Hamamatsu, read out by a row-column signal processing board. Two analytical event reconstruction algorithms were evaluated: rise-to-the-power with k=2 (RTP2) and k=3 (RTP3).

The detector was exposed to both a sealed 228Th source and a 67.5 MeV proton beam at a current of 100 pA. Floodmaps were obtained using both RTP2 and RTP3 methods to resolve the 8×8 matrix of the crystal under laboratory source irradiation. Similar results were obtained under proton beam irradiation, showing the robustness of this detector concept.

In this contribution we demonstrate for the first time the ability of a pixelated pure Cherenkov detector to provide spatial resolution information in clinically relevant proton beam conditions. The prompt emission of Cherenkov light and exclusive sensitivity to highly energetic PGs offer a very high count rate capability, effective background rejection, and capacity to multiplex signals, enabling to use less channels and low power readout electronics. Future work will focus on quantitative floodmap quality metrics, detector modeling to optimize the detector geometry, and acquisition of additional data in the proton beam line at higher proton energies and beam currents.

Abstract

Accurate proton range verification (PRV) in proton therapy (PT) is an unmet clinical need and is essential to exploit the full potential of PT to maximize treatment effectiveness and minimize toxicity. We present a Monte Carlo (GATE 10) study of a Cherenkov-based prompt gamma imaging system combining an array of PbF2 crystal detectors with a MURA coded-aperture collimator for real-time PRV. The detector response was studied through detected Cherenkov photon distributions generated by prompt-gammas with energies ranging from 0.5 MeV to 7.0 MeV in steps of 0.5 MeV. A threshold of 15 detected Cherenkov photons was applied to reject low-energy background, which effectively suppressed 511 keV annihilation gammas and sub-MeV contributions while retaining the prompt gammas of interest. Image reconstruction was performed using the Maximum Likelihood Expectation Maximization algorithm, with the system matrix computed with 4.4 MeV point-like sources. The imaging performance was validated on isotropic gamma point sources in both 1D and 2D coded-mask configurations across a field of view of ~130 mm. A direct comparison between discrimination based on energy deposition (E > 1 MeV) and discrimination based on the number of detected Cherenkov photons (nckv ≥ 15) showed comparable performance, with position residuals consistent with zero within statistical uncertainties in both cases. For the proton beam measurements, background rejection was performed exclusively via the Cherenkov photon count threshold. Under realistic proton beam conditions, the distal fall-off position was reconstructed with a systematic residual below 1.5 mm and a statistical precision of less than 2 mm for beam intensities above 10^8 protons, corresponding to approximately 10 ms of irradiation at a standard proton current of 2 nA (1.25 × 10^10 protons/s). This work presents the concept and shows the feasibility of using Cherenkov-based coded-aperture imaging for PRV by means of a simulation framework.

Abstract

Purpose: We are developing a Personalized Remote Radiation Tracking Portable Organ Dosimetry Device (PRRT PODD) for at-home monitoring of patients receiving radiopharmaceutical therapy (RPT). We report on an FPGA-based data acquisition system capable of wireless communication in support of this goal.

Methods: Our acquisition system supports16-radiation detectors and outputs an energy histogram for each using a time-over-threshold (ToT) energy measurement. The electronics consists of a custom analog board that converts each detector's analog signal into a digital ToT signal; an FPGA board for signal processing; and a microcontroller board that serves as the system controller. The microcontroller communicates with the FPGA via UART to retrieve energy histogram data, manages system configuration parameters, and provides Bluetooth Low Energy connectivity to a mobile Android app. The electronics fits within the PODD's base assembly and can operate on cell phone battery power. Each detector has a small thermistor for individual probe temperature monitoring and to characterize MPPC gain versus temperature. An Android app was developed to control data acquisition and wireless transfer of data to a remote workstation. The detector and electronics acqusition system was tested using Tc-99m, Na-22 and Lu-177 radioactive sources at clinically relevant counting rates.

Results: Sixteen channel operation of our FPGA-based data acquisition system has been validated using a variety of radionuclides. The output properties of the probes have been characterized versus temperature to enable post acquisition normalization of signals.

Conclusion and future work: A compact, wireless 16-channel gamma spectroscopy system for remote monitoring of Lu-177 RTP was designed and tested. Future work includes implementing real-time temperature compensation based on continuous temperature readings, ensuring stable operation without post-processing.

Abstract

Metal implants can degrade CT image quality and introduce artifacts that affect dose calculation in particle therapy. This study investigates attenuation images (μ-MLAA) reconstructed from time-of-flight PET data using maximum-likelihood reconstruction of attenuation and activity for metal artifact reduction. The linearity of a calibration curve relating CT number to relative electron density was first evaluated using a PMMA phantom with metal and tissue-equivalent inserts. Metal artifacts were then studied in a water phantom containing a Ti6Al4V total endoprosthesis (TEP) implant. μ-MLAA attenuation images reconstructed from PET list mode data and CT images reconstructed using iterative metal artifact reduction (iMAR) were evaluated using gamma index analysis (10%, 1 mm) relative to an artifact-free reference slice. The calibration curve remained linear in the presence of metal inserts ($R^2 > 0.999$). For the TEP phantom, μ-MLAA images achieved a higher gamma pass rate (96.3%) than iMAR CT (70.8%). Using the calibration curve, the relative electron density of the TEP shaft was estimated as $n_{e,rel} = 3.58 \pm 0.12$ corresponding to a 3.5% deviation from reported reference values. These results indicate the potential of μ-MLAA images for reducing metal artifacts and supporting implant characterization in radiotherapy imaging.

Abstract

PET-based range verification in ion-beam therapy requires decay correction for a depth-dependent mixture of positron emitters. We introduce a range-verification-oriented carbon-ion PET workflow that partitions beam-axis reconstructions into axial slices and fits post-beam-off time-activity curves with four fixed-half-life components (^{11}C, ^{15}O, ^{10}C, ^{13}N); the small ^{13}N term (~0.4%) was grouped with ^{11}C for comparison. The experiment contained 120 reconstructed 10-s frames, and corresponding GATE simulation modeled 221.48 MeV/u carbon ions with 2.0 x 10_7 primary particles and seven positron-emitting nuclides. Across 35 accepted PET slices (R^2 >= 0.9), fitted fractions were 82.6%, 12.1%, 4.9%, and 0.4%, showing clear ^{11}C dominance. After converting fitted amplitudes to observation-window counts, plateau PET fractions were 77.5%, 14.5%, and 8.0%, versus grouped simulation values of 63.2%, 27.1%, and 9.7% for ^{11}C+^{13}N, ^{15}O+^{14}O+^{17}F, and ^{10}C. Carbon-ion PET agreement is therefore nuclide dependent: ^{10}C showed the smallest residual bias after correction, whereas long-lived carbon/nitrogen activity remains high and oxygen-group activity remains low. This nuclide-aware comparison reveals isotope-group-specific discrepancies that total-activity range metrics cannot localize.

This work has received financial support from the IIS La Fe through the VLCBIOMED FARO project and the SO project CEX2023-001292-S funded by MCIU/AEI, as well as support from INNAVA2/2023/8-Potenciación (UCIE-IFIC) and Triad Semiconductor, Inc.

Abstract

The IRIS group at IFIC-Valencia, as part of the FARO (Feasibility of Adaptive Surface-Guided Radiation Oncology) project, funded under the VLC-BIOMED 2024 call (AP2024VLC-01), has developed a prototype to ensure the reproducibility of patient positioning, movement management in oncology applications and correlate the patient position across different scans. The system, based on Lighthouse v2 technology, uses base stations that emit infrared light and detectors that record these pulses. Experimental measurements at La Fe University and Polytechnic Hospital have been carried out using a torso phantom coupled to a motor that emulates different respiratory patterns. The results show that our non-invasive prototype is capable of calculating static position and reproducing respiratory movement with millimeter accuracy.

Abstract

Accurate in vivo dose range verification is critical in proton therapy due to uncertainties in beam range. Prompt gamma imaging (PGI) is promising because PG emissions correlate with the Bragg peak. However, conventional detectors can suffer from signal pile-up under high-intensity proton beams. Cherenkov detectors are attractive for PGI due to their selective gamma sensitivity, ultrafast response, and high count-rate capability. In this work, a PGI system based on PbF_2, a pure Cherenkov-emitting material, was simulated, and a multilayer perceptron (MLP) model was employed to predict proton range and one-dimensional dose distributions. The detector comprises a 32 × 32 PbF_2 crystal array coupled to a silicon photomultiplier (SiPM) array, with a knife-edge slit collimator providing one-dimensional PG projections. Proton beams from 70 to 120 MeV in 10 MeV intervals were simulated in a PMMA phantom using Geant4, and 1000 PG profiles per energy were generated via Poisson resampling. The MLP was trained on 70–120 MeV beams (80% training, 20% validation), while intermediate energies from 75 to 115 MeV (in 10 MeV intervals) were reserved for testing. Predicted dose distributions agree well with ground truth, achieving sub-millimeter proton range accuracy and mean relative errors (MRE) of 0.6–2.4%. These results demonstrate the feasibility of combining Cherenkov-based PGI with machine learning for accurate dose and range prediction, supporting future real-time, beam-by-beam verification in proton therapy.

Abstract

Post-thyroidectomy whole-body imaging after Iodine-131 administration in differentiated thyroid cancer is performed to verify biodistribution, identify thyroid bed remnants, detect locoregional and distant metastases, and support patient-specific dosimetry. The clinical standard, planar scintigraphy with a high-energy parallel-hole collimator, suffers from photon collection efficiency below 1% and depth ambiguity that can mask small remnants. We present a GATE/Geant4 Monte Carlo comparison of a clinical planar gamma camera and a compact handheld silicon/cesium iodide Compton camera at the 364 keV photopeak of Iodine-131 This translates into shorter acquisition times in clinical practice. Preliminary results indicate a sensitivity advantage of 30% for the Compton camera over the gamma camera in planar mode. The handheld geometry enables point-of-care bedside imaging of high-activity post-therapy patients, with potential to transform post-radioiodine therapy monitoring and dosimetry in thyroid cancer.

Abstract

Patient-specific dosimetry in peptide receptor radionuclide therapy (PRRT) using ^{177}Lu-DOTATATE commonly requires multiple quantitative SPECT/CT acquisitions to estimate time-integrated activity and absorbed dose distributions. Although multi-time-point imaging improves kinetic characterization, it increases clinical workload and patient burden. Single-time-point (STP) dosimetry approaches have therefore been proposed as practical alternatives, although conventional analytic STP methods may have limited accuracy in heterogeneous activity distributions.

In this work, CNN-based voxel dosimetry frameworks for ^{177}Lu-DOTATATE SPECT/CT were compared against conventional Hänscheid-based STP dosimetry. Quantitative SPECT/CT datasets from 44 paediatric treatment cycles were retrospectively analysed. Reference voxel-level absorbed dose maps were generated using multi-time-point dosimetry and GATE Monte Carlo simulation. Conventional STP dosimetry was performed using the Hänscheid formalism and a GATE-derived dose voxel kernel (DVK). A 3D U-Net architecture was used to estimate voxel-level absorbed dose maps from co-registered activity and density distributions using either a single 96 h activity input or paired 4 h and 120 h activity inputs.

CNN-based dosimetry demonstrated reduced organ-level absorbed dose deviations across the liver, spleen, kidneys, and tumour volumes relative to conventional STP dosimetry. Mean voxel-wise NMAE and NRMSE values decreased from 45.0 % and 54.3 % for conventional Hänscheid-STP dosimetry to 20.6 % and 27.4 % for CNN-STP dosimetry using a single 96 h activity input. The CNN model using paired 4 h and 120 h activity inputs further reduced these values to 18.8 % and 25.1 %, respectively. Improved preservation of heterogeneous tumour absorbed dose distributions was additionally observed in dose-volume histogram analysis.

Abstract

Positron emission tomography has been routinely used over the past 20 years for treatment delivery monitoring in charged particle radiotherapy. Based on previous work from our group on Monte Carlo simulations of real patient treatment plans, we report on the design and characterization of detector modules and readout electronics of a dedicated dual head PET system for treatment verification in proton therapy. The detector modules are made of LYSO:Ce matrices optically coupled to silicon photomultiplier matrices, with custom-designed compact readout electronics based on the 16-channel HRFlexToT ASIC, developed by our group in collaboration with the University of Barcelona. Each 64-channel detector module is read out by 4 ASICs, followed by an FPGA which records the time stamp of each event with respect to a global clock using a coarse and a fine counter, and digitizes the time-over-threshold output of each individual channel. Results from the characterization of the detector modules under irradiation of a 22Na source have shown that all channels are readout independently, with energy spectra for all channels yielding an average 16% energy resolution at the 511 keV photopeak. The time stamp of each event was calculated at FPGA level down to 87 ps binning, allowing time-of-flight PET image reconstruction. Moreover, individual readout of all channels allows the identification of intercrystal scatter events. We are currently developing a small prototype PET system based on these detector models and readout electronics to evaluate different treatment verification methods in proton therapy.

Characterization of Prompt Gamma-Ray Emission for Helium-Ion Beam Range Verification: A Monte Carlo Study (#2288)

Weigang Duan, Hongyang Zhang, Jiali Yan, Zhengyang Zhao, Shi Wang, Zhaoxia Wu, Hui Liu, Yaqiang Liu

Tsinghua University, Beijing, China

This work was supported in part by the National Key Research and Development Program of China (No. 2022YFC2402002, No. 2022YFC2403802), and National Natural Science Foundation of China (No. 12205166)

Abstract

Prompt gamma imaging is a promising technique for *in vivo* range verification in particle therapy. Compared with protons, Helium-ion (He^{2+}) beams may produce prompt gamma (PG) emissions different from proton beams, affecting energy-window (EW) selection and range-positioning performance. This study investigates the PG energy spectra, EW-dependent yields, and spatial distribution features of He^{2+} irradiation in a homogeneous PMMA phantom.

Monte Carlo simulations were performed using GATE for He^{2+} pencil beams from 70 to 230 MeV/u. Secondary gamma rays generated within the phantom were recorded using a *PhaseSpaceActor*, including their production positions, kinetic energies, direction vectors, and particle information. The PG spectra were analyzed and compared with proton-induced spectra. Several energy windows were selected according to characteristic spectral regions, and their PG yields, longitudinal distributions, and range-positioning performance were evaluated using *Falloff50%*, *Falloff80%*, and *Steepest Falloff* metrics.

The simulations showed He^{2+} irradiation produced substantially higher PG yields than proton irradiation over the investigated energy range, while the main spectral peaks appeared at similar energies. For He^{2+}, PG yield increased with incident energy in all selected windows. The broad 1.9–8 MeV window provided the highest yield and best statistical stability, whereas narrower characteristic windows showed stronger energy specificity but lower counting statistics. EW selection also affected the distal fall-off shape and the derived positioning value. Overall, the 1.9–8 MeV window combined with the Steepest Falloff metric provided the most robust PG range-positioning performance, supporting the development of helium-ion PGI range verification strategies.

This work was supported in part by the National Natural Science Foundation of China (12505396).

Abstract

Time-integrated activity (TIA) estimation is essential for patient-specific Lu-177 SPECT dosimetry, but voxel-wise time–activity curve fitting remains computationally demanding because nonlinear kinetic models must be solved independently across many voxels. This study developed a GPU-accelerated voxel-wise kinetic modeling framework for rapid Lu-177 SPECT TIA estimation. Four serial post-therapy SPECT/CT scans from anonymized Lu-177 DOTATATE datasets were analyzed. The framework used a hierarchical TAC model library, including one mono-exponential model and three bi-exponential variants, to characterize different uptake and clearance patterns. Model selection was performed using the Akaike information criterion, and voxels with insufficient fitting quality were processed using trapezoidal integration with tail extrapolation. GPU acceleration was implemented through batched voxel-wise optimization using CuPy-based array operations and compared with a CPU-based Levenberg–Marquardt implementation. Evaluation included fitting quality, model-selection distribution, agreement with dataset-provided reference TIA maps, organ/lesion-level relative error, and computation time. The GPU implementation preserved the CPU-derived model-selection distribution, with 60.7% mono-exponential, 31.2% bi-exponential, and 8.1% trapezoidal fallback voxels. The median regional voxel-wise fitting R^2 was 0.848. Relative differences from reference TIA maps were 4.2% for kidneys, 3.5% for spleen, 2.7% for liver, and 8.5% for tumor lesions. Computation time decreased from 552.1 s to 18.5 s per patient, corresponding to approximately 30-fold acceleration. These preliminary results support the technical feasibility of GPU-accelerated voxel-wise TAC fitting for practical Lu-177 SPECT dosimetry, although validation in larger multi-patient datasets remains necessary.

A Three-Stage Scintillator-Compton Camera for BNCT: From Point-Source Resolution to Phantom Reconstruction (#2560)

Sergio López Martínez, Catarina Veiga, Robert Speller, Robert Moss

University College London, Department of Medical Physics and Biomedical Engineering, London, UK

Abstract
Boron Neutron Capture Therapy (BNCT) requires accurate in-vivo dose verification, yet current clinical methods rely on indirect blood-based boron concentration estimates that introduce substantial inter-patient variability. Imaging the 478 keV prompt gamma ray emitted during boron-10 neutron capture offers a direct route to real-time dose mapping. However, this requires a detector capable of efficient reconstruction at high gamma energies in the presence of significant background.

Building on our previously reported scintillator-based Compton camera concept [1], we present the full computational characterisation of a three-stage system comprising scintillator cylinders arranged in a three-dimensional spherical array. The non-planar geometry offers multi-directional cone orientations, improving global spatial resolution compared to conventional planar designs. Geant4 Monte Carlo simulations were used to model a realistic BNCT irradiation scenario [2], incorporating a modified Snyder head phantom with clinically representative boron concentrations (25 ppm brain / 65 ppm tumour) [3].

Reconstruction performance is evaluated across scenarios of increasing complexity: an idealised point source, a distributed gamma-ray source, a treatment-like gamma source, and a full phantom simulation. This progressive approach illustrates how reconstruction quality is affected by increasing complexity and the high neutron-induced background inherent to BNCT environments, providing insight into the current limitations of the design and potential strategies to address them. These results establish a validated simulation framework for a scintillator-based Compton camera tailored to BNCT prompt gamma imaging, providing the foundation for forthcoming experimental characterization and clinical translation.

Abstract

Selective internal radiation therapy using ^{90}Y microspheres provides targeted treatment of liver malignancies, with post-therapy PET enabling treatment verification and voxel-based dosimetry. Quantitative ^{90}Y PET imaging is challenged by a low signal-to-background ratio. The internal pair production branching ratio of ^{90}Y is low, yielding a weak 511 keV annihilation photon signal amid background contributions from bremsstrahlung following β^- decay and intrinsic radiation from ^{176}Lu in PET systems constructed with LYSO scintillation crystals. These background events increase random coincidences and degrade spatial localization and dosimetric accuracy. This study evaluated the effect of PET energy window selection on ^{90}Y radioembolization dosimetry using standard (425-650 keV) and narrow (480-542 keV) energy windows. Six patients underwent post-therapy PET/MR imaging. Images were reconstructed using TOF-OSEM, and absorbed dose distributions were calculated using local deposition modelling. Randoms fraction, apparent activity outside the perfused volume, dose-volume histograms, and dose-volume metrics were compared between protocols. The narrow-window protocol reduced the randoms fraction from 91 ± 3% to 60 ± 10% and apparent activity outside the perfused volume by 51 ± 16%, indicating reduced background contamination and improved confinement of the reconstructed activity distribution. Mean absorbed doses to the tumour and healthy liver were preserved, and healthy liver $V30$ decreased by 13 ± 8%. Tumour $D70$ changed by -15 ± 33%, and tumour dose redistribution effects varied substantially between patients without a consistent directional trend. These findings demonstrate that narrow-window PET acquisition improves activity localization in ^{90}Y radioembolization while preserving overall absorbed dose estimates and may influence patient-specific voxel-based dosimetry.

Abstract

Particle therapy exploits the Bragg peak for precise dose deposition, yet the high-LET characteristic demands accurate real-time range verification and dose distribution monitoring. Compton cameras offer a promising collimator-free solution for the prompt gamma imaging induced during treatment. In this work, a Compton camera is constructed by using $Gd_3Al_2Ga_3O_{12}$:Ce (GAGG) scintillator coupled with silicon photomultiplier (SiPM) arrays. The scatter and absorber layers are both constructed from high-light-yield, high-energy-resolution GAGG with optimized geometry. An energy resolution of ~8% FWHM is obtained for 511 keV gamma rays, while the position resolution is 1.5 mm (scatter layer) and 2.0 mm (absorber layer) in both x and y directions. The scatter layer retains the capability for dual-ended readout, with an expected DOI resolution of ~2.5 mm. Image reconstruction is performed using GPU-accelerated LM-MLEM. Laboratory measurements with a ^{22}Na source demonstrate that an angular resolution of ~7° at 511 keV and ~6° at 1274 keV was achieved. Future work will focus on proton/carbon ion beam experiments and scaling the effective detector area to 100 mm × 100 mm.

Abstract

This study presents a data-driven framework for optimizing dosimetry regimens in radiopharmaceutical therapy using *in vivo* data from [^{177}Lu]Lu-PSMA-617-treated murine models incorporating therapy resistance. Experimental data demonstrated improved long-term outcomes for cumulative (3 × 10 MBq) and de-escalation (20 MBq + 10 MBq) regimens compared with conventional single-dose (30 MBq) and escalation (10 MBq + 20 MBq) schedules. Building on these findings, additional treatment regimens were evaluated in silico to identify combinations of favorable therapeutic characteristics. Dose-rate kernels derived from dynamic SPECT/CT imaging were used to calibrate an integrated dose–response and tumor growth model. These kernels captured both the temporal evolution of dose rates following treatment and spatial intratumoral heterogeneity through region-specific dose quantiles. Therapy resistance across treatment cycles was incorporated using generalized dose-rate patterns derived from experimentally observed relationships between treatment response and previously administered activity ratios. The spatial distribution of dose-rate regions used for kernel generation was best described by an exponential decay model, yielding a lower Akaike Information Criterion (AIC: −139 ± 31) than alternative distributions. Simulations identified the 3–2–1 (15, 10, 5 MBq), 2–1–1 (15, 2 × 7.5 MBq), and 2–2–1 (2 × 12, 6 MBq) regimens as outperforming the experimentally tested schedules. These results demonstrate the potential of simulation-based optimization to support the design of biologically informed radiopharmaceutical therapy regimens and provide a framework for systematic *in silico* treatment planning.

[1] University of Brest, LaTIM, INSERM-UMR1101, Brest, France; [2] Brest Hospital University, Radiotherapy Department, Brest, France

Abstract

While recent deep learning techniques for accelerating Monte Carlo (MC) radiotherapy dose calculation have shown promising results, most state-of-the-art methods rely on a denoising paradigm. This approach aims to

predict a high-sampling (HS) reference dose map from a fast low-sampling (LS) input. However, information loss and stochastic noise in LS inputs often limit the accurate recovery of fine structural details and dose gradients, and may lead to hallucinations. To address these limitations, we propose a novel learning framework, Energy-Shifting, which reconstructs a time-intensive polyenergetic HS dose distribution from a GPU-accelerated monoenergetic dose map. Our results demonstrate that this method significantly outperforms conventional denoising approaches in accuracy.

MIC-15-372

Human Single Time Point Dosimetry Using Weight-Based Extrapolated Mouse Effective Half-Life (#3228)

Muath Almaslamani[1,2], Jingyu Yang[1], Ilhan Lim[2,3], Kwang il Kim[1,2], Sang Keun Woo[1,2]

Abstract

Image-based dosimetry requires multiple-time-point (MTP) imaging to estimate the time-integrated activity (TIA), which can be challenging to implement in clinical practice. Moreover, Mouse-to-human extrapolation methods produces large errors. This study aimed to evaluate single-time-point (STP) dosimetry approach using extrapolated human effective half-life derived from preclinical activity scaling based on body weight and organ mass. Six patients underwent where administrated with ^{64}Cu-DOTA-rituximab and underwent MTP PET/CT imaging at 1, 24, and 48 h post-injection (p.i.), while four mice were imaged at 1, 24, 48, and 72 h p.i. Regions of interest were manually drawn for the kidney, liver, and spleen. Human MTP reference TIA was calculated using OLINDA with mono-exponential fitting. Mouse organ activity was converted to estimated human organ activity using body weight and organ mass scaling as: $(\%ID/organ)_{human}=(\%ID/g)_{mouse}\times(kg_{WB})_{mouse}\times(g_{Organ}/kg_{WB})_{human}$. Human TIA was then estimated from the extrapolated activity curve. In the proposed approach, the extrapolated human time–activity curve was used to derive the extrapolated human effective half-life. This effective half-life was then combined with the measured human organ activity from STP scan and TIA was calculated as following: $TIA=(A(T_{sc})/\ln(2))\times 2^{Tsc/Teff(extrapolated)}\times T_{eff(extrapolated)}$. [if gte msEquation 12]><m:oMath><span style='font-size: 10.0pt;line-height:107%;font-family:"Cambria Math",serif;mso-fareast-font-family: "Malgun Gothic";mso-fareast-theme-font:minor-fareast;mso-bidi-font-family: "Times New Roman";color:black;mso-themecolor:text1;mso-ansi-language:EN-US; mso-fareast-language:KO;mso-bidi-language:AR-SA'><m:r> </m:r></m:oMath><![endif][if gte vml 1]><v:shapetype id="_x0000_t75" coordsize="21600,21600" o:spt="75" o:preferrelative="t" path="m@4@5l@4@11@9@11@9@5xe" filled="f" stroked="f"> <v:stroke joinstyle="miter"/> <v:formulas> <v:f eqn="if lineDrawn pixelLineWidth 0"/> <v:f eqn="sum @0 1 0"/> <v:f eqn="sum 0 0 @1"/> <v:f eqn="prod @2 1 2"/> <v:f eqn="prod @3 21600 pixelWidth"/> <v:f eqn="prod @3 21600 pixelHeight"/> <v:f eqn="sum @0 0 1"/> <v:f eqn="prod @6 1 2"/> <v:f eqn="prod @7 21600 pixelWidth"/> <v:f eqn="sum @8 21600 0"/> <v:f eqn="prod @7 21600 pixelHeight"/> <v:f eqn="sum @10 21600 0"/> </v:formulas> <v:path o:extrusionok="f" gradientshapeok="t" o:connecttype="rect"/> <o:lock v:ext="edit"

aspectratio="t"/></v:shapetype><v:shape id="_x0000_i1025" type="#_x0000_t75" style='width:468pt; height:12.75pt'> <v:imagedata src="file:///C:/Users/muath/AppData/Local/Temp/msohtmlclip1/01/clip_image001.png" o:title="" chromakey="white"/></v:shape><![endif]. The proposed STP approach reduced the estimation error for kidney from 88.7% with the conventional extrapolation approach to 29.0%, 40.6%, and 66.7% at 1, 24, and 48 h p.i., respectively. The corresponding errors decreased from 406% to 26.8%, 35.1%, and 65.3% for the liver, and from 480% to 42.2%, 57.7%, and 76.2% for the spleen, respectively. These results demonstrate that incorporating measured human STP activity with extrapolated human effective half-life improves TIA estimation and provide a practical dosimetry approach when full MTP imaging is not feasible.

Abstract

Respiratory phase mismatches between PET and CT commonly cause artifacts in PET/CT, especially at lung–liver and lung–spleen interfaces. Since CT captures a single respiratory phase while PET reflects an average over breathing, this misalignment leads to attenuation correction errors and inaccurate lesion quantification, particularly near the liver dome. We propose a deep learning framework that uses PET-based pseudo-CT to guide deformable CT-to-PET alignment. A retrospective dataset of 10 18F-FDG exams with respiratory phase mismatch (banana) artifacts, scanned on a Total-Body BGO-based PET/CT scanner, was used for evaluation. A previously trained 3D residual neural network was used to generate pseudo-CT images from non-attenuation corrected (NAC) PET images. The pseudo-CT images, inherently aligned with the PET data, were then used as a reference for deformable registration of the CT images. The original and registered CT images were used for attenuation correction and reconstruction of the PET data using a BSREM algorithm. Regions of interested were placed in dome of the liver to quantitatively measure the SUV changes in those regions affected by the artifacts. Compared to baseline PET/CT without correction, the proposed method effectively reduced or eliminated respiratory-induced PET/CT misalignment artifacts were significantly reduced or eliminated. Quantitatively, the method achieved improvements in liver SUVmean towards the expected values. By leveraging the native alignment between PET and the generated pseudo-CT, the method avoids direct multimodal registration and instead enables accurate deformable alignment of CT to PET space. This approach improves attenuation correction and quantitative accuracy, with potential to enhance diagnostic confidence in routine clinical PET/CT imaging

Investigation of Image Quality Gains Using Variable Time Windows in Long-Axial PET Systems (#1914)

Yue Chen, Yucun Hou, Jianyong Jiang

Beijing Normal University, school of physics and astronomy, Beijing, China

This work was supported by the National Natural Science Foundation of China (No. 12475336)

Abstract

The extension of the axial field-of-view (AFOV) represents a transformative advancement in PET, offering superior sensitivity and enabling ultra-low-dose 4D imaging. However, the increased AFOV necessitates wider acceptance angles and correspondingly larger coincidence time windows, leading to a substantially higher proportion of random coincidence events compared to conventional scanners. While traditional random correction relies on noisy, sparse delayed coincidence sinograms, the singles-rate method has been approved as a superior alternative for long-axial FOV (LAFOV) systems. A critical yet underexplored challenge in LAFOV PET is the significant variation in the required time window across different ring differences. Although object-specific customized windows have shown promise in short-axial systems, their application to total-body PET remains largely unoptimized. In this study, we propose a novel reconstruction strategy utilizing a variable time window tailored to specific ring differences to minimize random fractions. Using GATE simulations of a 1.5-m total-body PET system (uMI Panorama GS), we designed and evaluated a variable time window set based on practical coincidence time resolution (CTR). This approach was benchmarked against a standard fixed window (6.0 ns) and a 3-step window (4.7, 6.2, and 8.3 ns). Systematic analysis of simulated coincidence data reveals that the variable window design significantly reduces the random fraction. Comparative reconstructions of a uniform cylinder, NEMA, and torso phantoms demonstrate that this reduction directly translates to lowered image noise levels and enhanced signal-to-noise ratios within a consistent reconstruction framework. These findings establish that ring-difference-specific time windows provide a robust technical pathway for maximizing the quantitative performance of next-generation LAFOV PET systems.

Evaluation of TOF-DOI Crystal Topologies for the HD-MetaPET MRI Insert (#2140)

Thore Meyer[1], Giulia Terragni[2], David Schug[1,3], Yannick Kuhl[1], Bjoern Weissler[1,3], Eike Gegenmantel[3], Oliver Muelhens[3], Harald Radermacher[1], Marco Pizzichemi[2,4], Etiennette Auffray[2], Volkmar Schulz[1,3]

[1] RWTH Aachen University, Chair of Imaging and Computer Vision, Aachen, Germany; [2] CERN, Geneva, Switzerland; [3] Hyperion Hybrid Imaging Systems GmbH, Aachen, Germany; [4] University of Milano-Bicocca, Milan, Italy

This work is sponsored by the BMFTR, contract numbers 13GW0609A, 13GW0609B, 13GW0621A and 13GW0621B. Part of this work was performed in the framework of Crystal Clear Collaboration.

Abstract

The HD-MetaPET project is developing a high-resolution positron emission tomography insert for simultaneous magnetic resonance imaging. The insert will consist of 120 Hyperion Visor Max detector tiles with an area of 56.5 x 56.5 mm^2, arranged in two semi-circles and coupled to LYSO:Ce crystal scintillators. A crucial optimisation parameter for the upcoming system performance is the crystal topology. This study evaluates Time-of-Flight and Depth-of-Interaction positioning performance across several crystal topologies: continuous slabs, pseudoslabs, and pixelated arrays with a light guide coupled to the face opposite the photosensitive detector. The study utilizes the Hyperion Visor Max and a custom development board, both featuring the TOFPET2 ASIC. Experimental measurements are performed using a ^{22}Na point source. The preliminary results with crystals of different materials show that pixelated arrays with light guides outperform continuous slabs. Specifically, pixelated designs achieved a Coincidence Time Resolution of ≈235 ps, compared to >400 ps for the slabs. The results indicate that the pixelated designs utilizing the light guide also demonstrated superior accuracy in the evaluation of the Depth-of-Interaction. The pixelated light-guide topology shows promising performance, circumventing the traditional compromise between spatial depth accuracy and timing resolution. Consequently, this configuration emerges as a good candidate for integration into the upcoming HD-MetaPET scanner. While these preliminary results are promising, the comprehensive evaluations utilizing final-scale crystals of the same material and the final scanner electronics will be presented at the conference.

Abstract

Dynamic PET imaging enables tracer kinetics characterization, offering complementary quantitative insights beyond static imaging. The advent of Long Axial Field-of-View (LAFOV) scanners, with high sensitivity, has renewed interest in kinetic modelling by enabling whole-body dynamic imaging in clinical settings. However, acquisitions can last up to 1 hour, limiting adoption due to reduced throughput. Clinically, reporting relies on late-phase images (1-hour post-injection), whereas kinetic modelling requires data from injection, creating a conflict between clinical requirements and feasibility. This work investigates whether dynamic protocols can be shortened to 20 minutes post-injection while preserving clinically relevant information by predicting late-phase time-activity curves (TACs) from early dynamic data. The cohort included 107 subjects imaged with ^{18}F-FDG, yielding 20,903 TACs extracted from multiple anatomical structures. Four approaches were compared: a three-exponential model, two-tissue compartment model (2TCM), a gated recurrent unit encoder-decoder, and a novel Neural Ordinary Differential Equation framework (NODE). At 60 minutes, all methods showed near-zero median residuals. Over 20–60 min, NODE outperformed competing approaches with the lowest root mean squared error (0.096) and χ^2 (0.43), and the highest concordance correlation coefficient (0.40), with reduced variability across TACs. Overall, prediction of late-phase PET information from 0–20 min data appears feasible. NODE provided the most accurate and stable results, although 2TCM remained competitive at 60 min, suggesting benefits from incorporating physiological priors. Future work will extend the analysis to voxel-wise reconstruction, with preliminary results showing promising outcomes, and will examine kinetic parameter consistency between observed early dynamics (0–20 min) and full predicted dynamic data (0–60 min).

This work was supported by the Science and Technology Development Fund of Macau (0178/2024/AMJ) and University of Macau (CG2026-FST).

Abstract

Partial volume effects (PVE) degrade quantitative accuracy and blur boundaries in PET. MR-guided partial volume correction (PVC) can mitigate PVE, but it requires anatomical information from MR, which may be unavailable. This work aims to develop a 2-stage deep learning-based PET to MR synthesis framework, SADCA-ResDiff, to provide structural priors for MR-guided PVC in 18F-AV45 amyloid brain PET. A total of 135 pairs of 18F-AV45 PET and MR were selected from ADNI [1]. A coarse MR is first generated from PET using a dual cross-attention UNet, while a residual diffusion network with an edge-aware mechanism is applied to refine the coarse MR. Joint mutual information, diffusion, reconstruction, and structure-aware symmetric consistency losses derived from a pretrained MR segmentation model were used to optimize the 2-stage network. Synthesized MR was segmented into gray matter (GM), white matter (WM), and cerebrospinal fluid masks using FSL [2] and applied to the Iterative-Yang (IY) PVC [3]. SADCA-ResDiff was compared with DeepPVC [4], using standard IY as reference. Structural similarity index (SSIM) and peak signal-to-noise ratio (PSNR) was measured on the whole brain while regional error was evaluated using relative mean absolute error (RMAE) for GM and WM. Wilcoxon signed-rank test was used for statistical comparison.

SADCA-ResDiff achieved the highest SSIM and PSNR among all methods (0.97±0.02 and 32.62±3.43dB), significantly outperforming DeepPVC (0.93±0.02 and 27.95±3.67dB) and origin PET (0.90±0.02 and 26.73±3.89dB) (all $p<0.05$). It also yielded the lowest RMAE in GM and WM (0.12±0.05 and 0.08±0.05), compared with DeepPVC (0.14±0.04 and 0.15±0.03) and origin PET (0.16±0.04 and 0.15±0.03).

SADCA-ResDiff provides effective anatomical guidance for PVC in amyloid PET, offering a practical solution for MRI-free PET quantification.

Abstract

A locally developed database of human brain studies from 113 subjects has been used to develop and train convolutional neural networks (CNNs) for attenuation correction in SPECT. All subjects underwent brain perfusion SPECT imaging studies with ^{99m}Tc-ECD, an X-ray CT scan, and MRI. Images were preprocessed for anonymization, removal of the table in CT, co-registration, and spatial and intensity normalization. Deep learning architectures encompassed U-Net, Residual U-Net, Attention U-Net and Residual Attention U-Net. Three methods were evaluated: (a) direct mapping of uncorrected SPECT to corrected SPECT, (b) multisequence MRI scans to synthetic CT (sCT) mapping, followed by iterative reconstruction with sCT attenuation correction, and (c) CNN reconstruction using sinograms to directly generate attenuation-corrected SPECT images. To evaluate the attenuation-corrected images, the mean square error (MSE), peak signal-to-noise ratio (PSNR) and structural similarity index (SSIM) were calculated. Attenuation corrections were successfully applied using three different approaches, addressing various clinical scenarios found in clinical medical equipment that does not have CT for attenuation correction, such as dedicated SPECT or SPECT/MRI.

Assisting Total-Body Multiplexed PET Separation Using Synthetic Paired Data (#1368)

Denis Prokopenko, Andrew J. Reader

King's College London, London, UK

This work was funded by the Australian Research Council (ARC) DP230102070.

Abstract

Multiplexed positron emission tomography (mPET) remains limited by the challenge of separating overlapping tracer signals, as tracers produce indistinguishable same-energy photon pairs.

Existing deep learning-based separation methods are constrained by the limited real data availability, particularly in the context of total-body imaging.

In this work, we propose a framework for training total-body dual-tracer mPET separation models using synthetic paired datasets generated from independent single-tracer acquisitions, and investigate the effect of synthetic data diversity on separation performance.

Two score-based generative models were trained to generate synthetic [18F]FDG and [18F]PSMA PET images conditioned on attenuation maps.

Complementary synthetic tracer images were combined with real PET acquisitions to construct paired dual-tracer datasets for training a Swin UNETR-based separation model.

Quantitative evaluation on dual-tracer combinations demonstrated the feasibility of the proposed framework and suggested that increased diversity of synthetic samples may improve separation robustness.

These results highlight the potential of generative augmentation as a scalable strategy for pretraining mPET separation models under limited paired-data availability.

Abstract

Diffusion models have shown strong potential for cardiac-gated myocardial perfusion single-photon emission computed tomography (CG MP-SPECT) denoising. However, centralized or fully federated diffusion training requires each client to process a complete high-capacity model, which may be impractical for resource-limited nuclear medicine departments. This study presents a multi-client split federated learning diffusion framework (SFLDiff) for resource-efficient CG MP-SPECT denoising. SFLDiff vertically partitions the diffusion network into lightweight client-side encoders and a server-side reconstruction module, enabling local clients to perform shallow feature extraction while computationally intensive generative restoration is executed on the server. This architecture reduced client-side GPU memory consumption from over 4300 MiB to approximately 257 MiB with a training time of 2950.39 s while maintaining competitive denoising performance. Experiments on 8-/16- cardiac gated datasets showed that SFLDiff achieved image restoration accuracy comparable to centralized and federated diffusion baselines and superior to standard split learning, particularly under high-noise gated conditions. These results suggest that multi-client split federated diffusion provides a practical quality–efficiency trade-off for deploying advanced generative denoising models in resource-constrained CG MP-SPECT environments.

Abstract

Dual-time-point positron emission tomography (PET) provides complementary temporal uptake information for lesion characterization, but delayed imaging increases examination time and clinical workload. This study proposes UCD-Net, a weakly supervised cyclic disentanglement framework for synthesizing delayed-pass PET from first-pass PET. UCD-Net decompose first-pass PET images into a delayed-equivalent component, a signal-dependent residual component, and a signal-independent residual component, followed by cyclic re-decomposition to improve latent-component separation. Reconstruction, zero-mean, identity-consistency, and noise-statistical constraints are used to preserve image content and suppress residual interference. A three-dimensional projection-excitation module captures global spatial statistics along depth, height, and width to enhance anatomical consistency. Real delayed PET images are incorporated as weak distribution-level guidance through a rank-based consistency loss, allowing the model to better recover delayed uptake patterns without direct image-to-image supervision. This retrospective study included 90 PET scans from 70 patients, including 86 ^{18}F-FDG PET scans and 4 ^{68}Ga-PSMA PET scans, divided into training, validation, and test sets. The weakly supervised UCD-Net was compared with its unsupervised backbone and four baseline models, including EDCNN, CGAN, U-Net, and CVF-SID. Across three test scenarios, the weakly supervised UCD-Net achieved the best performance, with RMSE values of 0.0333, 0.0365, and 0.0236. Compared with unsupervised UCD-Net, weak delayed-image guidance reduced RMSE by 17.2%, 20.8%, and 30.0%. These results suggest that UCD-Net can synthesize delayed-equivalent PET images from first-pass PET and may reduce dependence on additional delayed imaging.

Neural Radiance Field-Based Reconstruction of Object Changes in Stationary Computed Tomography with Linearly Distributed Sources

(#1936)

Haoyuan Qian[1], Yongshun Xiao[2]

[1] Tsinghua University, Department of Engineering Physics, Beijing, China; [2] Tsinghua University, Department of Engineering Physics, Beijing, China

This work was supported by Beijing Natural Science Foundation QY25007. I would like to thank Dr. Yongshun Xiao, Associate Professor at Department of Engineer Physics, Tsinghua University, for valuable guidance and support.

Abstract

This research aims to detect and reconstruct object changes using computed tomography (CT). We focus on stationary CT with linearly distributed sources (SLCT), which enables rapid projection data acquisition without mechanical rotation. However, due to the lack of sufficient angular coverage, SLCT inherently suffers from a severely limited-angle imaging problem, where direct reconstruction leads to strong anisotropic artifacts. To address this issue, we introduce the pre-change object as prior knowledge and propose two Neural Radiance Field (NeRF)-based change modeling strategies. The first method, Full-Object Nerf (FO-NeRF), continues optimization from a pre-trained NeRF representing the pre-change object, refining it into the post-change object. The second method, Change-Filed NeRF (CF-NeRF), explicitly models a change field and directly learns the residual component between the pre- and post-change objects. We validate the proposed methods on 2D simulated objects composed of simple geometric shapes. Experimental results demonstrate that, with prior constraints, both methods can successfully reconstruct object changes while effectively mitigating limited-angle artifacts. These results indicate that, by leveraging object priors within a NeRF-based representation, the highly ill-posed limited-angle reconstruction problem can be transformed into a more stable and tractable optimization problem, enabling reliable change detection and reconstruction under severely incomplete projection data.

Methods for Reconstruction Aware Completion of Partial PET Sinograms (#2029)

Ziad Burbar, Inki Hong

Siemens Molecular Imaging, Knoxville, USA

Abstract

A partial-detector-ring Positron Emission Tomography (PET) system may be an option to reduce cost and/or enable integration within another modality for multimodality imaging. In some use cases, the PET system may not be able to rotate continuously to collect all lines of response needed to form an image, yet a rapidly available image is still required for image quality control or organ-motion detection when the detectors are stationary. In this setting, missing angular coverage yields incomplete projection measurements and degraded reconstructions. This work describes a learning-based method to generate results equivalent to full-ring acquisition from partial-ring data This work proposes a reconstruction-aware sinogram completion network that predicts a full-ring-equivalent sinogram while enforcing consistency after tomographic reconstruction. This method combines supervision in projection space with an additional image-space objective computed after reconstructing the predicted sinogram using standard PET reconstruction operators, encouraging outputs that both match full-ring sinograms and yield accurate reconstructed images. By incorporating reconstruction consistency, the reconstruction-aware approach is intended to enable partial-ring systems to produce full-ring-equivalent sinograms that can be reconstructed with existing pipelines without modification, supporting more practical imaging workflows when mechanical rotation is constrained.

This work was supported by the Macao Polytechnic University under Grant RP/FCA-10/2025.

Abstract

Automated bone metastasis detection in whole-body bone scintigraphy (WBBS) is often hindered by subtle contrast, scale variation, and physiological interference. We propose an enhanced YOLOv11-based framework incorporating a symmetry-aware representation—utilizing ECC (Enhanced Correlation Coefficient)-registered mirrored images and difference maps—to model pathological asymmetry. To handle multi-scale lesions, we introduce a scale-sensitive architecture featuring a P2 detection branch and Efficient Multi-scale Attention (EMA). Furthermore, an extremity-specific refinement branch and an anatomical cross-view fusion strategy (integrating anterior/posterior projections) are employed to improve sensitivity in limbs and reduce single-view occlusion. Evaluated on 1,800 patient studies, our method achieved 0.959 recall, 0.820 precision and 0.785 mAP50, outperforming YOLOv8 and Faster R-CNN, particularly for small, low-contrast lesions. The exceptionally high recall demonstrates superior sensitivity to small and low-contrast lesions, highlighting the method's potential as a reliable screening tool to minimize missed diagnoses in clinical practice.

Abstract

Accurate Aβ PET/CT classification is critical for Alzheimer's diagnosis and anti-amyloid treatment eligibility, yet existing methods struggle to model higher-order inter-regionbrain relationships and handle class imbalance and per-class learning hardness. We propose HyperAβ, which constructs a 30 node brain-region hypergraph over SynthSeg-parcellated multimodal PET/CT features with 10 anatomically-defined hyperedges,and employs hypergraph convolution for higher-order multiregion interaction modeling. To address class imbalance and per-class learning hardness, we introduce GCA-D loss combining static per-class confidence calibration with EMA-based dynamic hardness tracking. Under 5-fold cross-validation, HyperAβ achieves ACC of 0.8784 and AUC of 0.9341, outperforming state of-the-art methods.

Abstract

Nasopharyngeal carcinoma (NPC) is common in southern China, Southeast Asia, and North Africa. Radiotherapy treatment planning (RTP) relies on magnetic resonance (MR) imaging and computed tomography (CT). MR provides superior soft-tissue contrast for target delineation, whereas CT provides electron density information for dose calculation. However, separate acquisition and subsequent registration of MR and CT not only increase time, cost, and radiation exposure, but also introduce registration and dosimetric errors. Diffusion model-based MR-to-CT synthesis offers an efficient, cost-effective, and radiation-free alternative for NPC radiotherapy. However, the nasopharyngeal region has highly complex anatomical structures. As a result, existing methods often fail to preserve anatomical details adequately and may suffer from mode averaging between adjacent slices, reducing slice-specificity and distributional separability. Accordingly, a wavelet-enhanced trajectory-refined flow matching model (WETR-FM) was proposed. A wavelet fusion convolution (WFConv) is introduced to strengthen the extraction of multi-frequency information in the feature space, particularly high-frequency structural details. A wavelet enhanced attention (WE-Attn) module is designed to enhance the network's ability to model critical multi-scale structural features through attention interactions among different frequency components. A trajectory refinement loss (TR loss) is incorporated to enlarge the differences among the denoising trajectories and terminal distributions of different slices. This helps alleviate distributional confusion between adjacent slices, while improving slice-specificity. Experimental results demonstrate that WETR-FM outperformed existing approaches (cycleGAN, sc-cycleGAN, pix2pix, DDPM, FM, SM) in terms of MSE and MAE by more than 35%, and improved by 4%-10% in PSNR. These findings demonstrated promising potential for application in NPC radiotherapy.

Abstract

Reducing positron emission tomography (PET) tracer dose lowers patient radiation exposure but degrades image quality and the quantitative accuracy of standardized uptake values (SUVs). Paired same-subject low/full-dose acquisitions
are impractical to obtain at scale, motivating unpaired image translation. Applying Contrastive Unpaired Translation (CUT)
to ultra-low-dose PET, we identify a quantitative failure mode in which the trained generator improves image appearance but
introduces high-uptake SUV underestimation that can exceed the bias of the unprocessed low-dose input itself. We interpret this
behavior as a mismatch between the fixed residual weighting of the intensity-space ℓ1 identity loss and PET's uptake-dependent
Poisson-derived noise. To address this, we propose PA-CUT (Poisson-Aware CUT), which replaces the ℓ1 identity loss with
one evaluated under the classical Anscombe transform, a Poisson-motivated variance-stabilizing reweighting of the identity term. A
multi-dose training scheme yields a single model across multiple dose reduction factors (DRFs). On the UDPET 2024 challenge
dataset, PA-CUT substantially reduces high-uptake SUV bias compared with CUT, with negligible changes in pixel-level and
perceptual quality.

Deep Learning with Physics-Corrected Histo-Images for Robust Low-Dose Scatter Correction on uMI Panorama GS (#2657)

Xu Zhang, Yihang Zhu, Liuchun He, Qing Ye, Yun Dong, Hao Zeng, Hancong Xu

United Imaging Healthcare, Shanghai, China

Abstract

Quantitative accuracy in PET relies heavily on effective scatter correction (SC), especially for long axial field-of-view (LAFOV) systems such as the uMI Panorama GS where low-count scenarios are increasingly prevalent. Conventional SC requires an emission map generated through iterative OSEM reconstruction, which is inherently sensitive to noise and degrades at low doses. Our prior work demonstrated that a deep learning (DL) approach using physics-corrected histo-images achieves high quantitative accuracy for SC under standard-dose conditions [2].

In this work, we extend this framework to low-dose scenarios on the uMI Panorama GS PET/CT system. We collected 220 static ^{18}F-FDG cases and 21 dynamic cases. Low-dose conditions were simulated by randomly downsampling events at seven dose levels (0.1%–100%). A U-Net was trained to predict emission maps from physics-corrected histo-images, with full-dose reconstructions as targets.

At standard dose, both the proposed and conventional methods achieved relative differences below 2% compared with the ground truth. At the 0.1% dose level, the conventional method showed organ VOI deviations approaching 10%, while the proposed method remained below 2% across all dose levels. In dynamic studies, the proposed method preserved time-activity curve accuracy at 0.5% dose and produced reliable Patlak Ki images at 1% dose. Combined with regularized reconstruction, the proposed method enables ultra-low-dose PET data to yield clinically usable images with high quantitative accuracy, demonstrating its potential for low-dose PET applications.

Abstract

This study proposes Quantum Barren-Plateau Correction via Information-theoretic Regularization (QBPCIR), a hybrid quantum-classical architecture for CT radiomics-based pancreatic lesion classification. A parameter-shift-rule diagonal quantum Fisher information matrix (QFIM) estimator quantifies per-class output curvature and adaptively amplifies minority-class gradient contributions to mitigate barren plateau-induced gradient suppression. Evaluated on 1206 training and 71 test portal-venous CT cases with 294 LASSO-selected PyRadiomics features, QBPCIR-VQC achieved AUC 0.916 and recall 0.859, outperforming a classical MLP (AUC 0.846) and a standard VQC (AUC 0.880), and approaching the recall of an expert radiologist reference (0.830). The BCE ablation confirmed that the inter-class Fisher trace asymmetry is a genuine quantum geometric effect, validating the information-theoretic rationale for the proposed correction

Abstract
Accurate organ segmentation in positron emission tomography (PET) is essential for quantitative analysis, treatment personalisation, and clinical decision-making. In current practice, organ masks are commonly derived from CT using tools such as TotalSegmentator (TS) and transferred to PET directly; however, PET–CT misalignment systematically degrades accuracy and biases downstream functional measurements. PET-native supervised approaches mitigate this misalignment but require costly expert annotation and lack generalisability to unseen organs or acquisition protocols. We propose a zero-shot vision-language refinement framework that adapts CT-derived anatomical priors to PET without any PET-specific training. TS masks are converted into multi-modal prompts for SAM3 — comprising organ bounding boxes, interior positive points, boundary negative points, and organ-specific radiological text descriptions — which are applied independently across axial, coronal, and sagittal views. A Prior-Anchored Refinement Gate (PARG) then constrains each SAM3 prediction by enforcing spatial overlap, area consistency, and eroded-core preservation with respect to the TS prior, suppressing anatomically implausible outputs. Evaluated on 12 held-out oncological PET-CT studies across liver, spleen, and bladder, our zero-shot refinement consistently outperforms TS, improving Dice from 0.744 to 0.835 for bladder, 0.936 to 0.941 for liver, and 0.870 to 0.879 for spleen. Our SAM3 features are further incorporated as auxiliary inputs to supervised training of nnUNet with very limited true labels. The resulting PET+TS+SAM3 configuration achieves Dice of 0.929 (bladder), 0.945 (liver), and 0.886 (spleen) with only eight annotated cases. These results demonstrate that our method effectively corrects PET–CT mismatch and offers a label-efficient, annotation-free pathway towards generalizable PET-CT multi-organ segmentation.

[1] Turku PET Centre, Turku University Hospital and University of Turku, Turku, Finland; [2] Tabriz University, Tabriz, Iran; [3] University MedicalCenter Utrecht, Department of Cardiology, DivisionHeart & Lungs, Utrecht, Netherlands

Abstract
Convolutional neural networks and vision transformers are increasingly applied to medical image classification, yet their comparative decision-making behavior under equivalent aggregate performance remains poorly understood. We trained a convolutional neural network equipped with convolutional block attention modules and a vision transformer from scratch to predict major adverse cardiac events from nitrogen-13 ammonia positron emission tomography myocardial perfusion polar maps in a cohort of 1,079 patients. Across 100 independent training runs, both architectures achieved statistically indistinguishable area under the receiver operating characteristic curve (both 0.90; Wilcoxon signed-rank p = 0.897), yet discordance analysis revealed significantly different binary predictions on specific patients (McNemar p = 0.0013). Using architecture-appropriate explainability methods —

gradient-weighted class activation mapping (the improved variant) for the convolutional network and attention rollout for the vision transformer — we propose a mechanistic hypothesis that the transformer's global self-attention integrates large-territory perfusion defects that the convolutional network's local spatial attention fails to aggregate. These findings demonstrate that equivalence in area under the curve does not imply decision equivalence, and motivate consideration of decision-level discordance when comparing architectures for clinical deployment.

We thank our colleagues from the Molecular Imaging Center and Dr. Christophe Carpentier for sharing the preclinical data used in this study

Abstract
Accurately quantifying radiotracer uptake and metabolic activity in a subject using positron emission tomography (PET) requires correcting for photon attenuation. An attenuation map, typically produced using a second imaging modality, is required for attenuation correction but can increase radiation exposure, operational costs, and reconstruction complexity. To mitigate these drawbacks, methods for generating attenuation maps from the non-attenuation-corrected (NAC) PET image using deep neural networks were proposed. Preclinical PET images of small animals present additional challenges for artificial attenuation map generation because the attenuation is low and the subjects are not rigid bodies, making anatomical structures less consistent and more prone to artifacts. A conditional Denoising Diffusion Probabilistic Model (cDDPM) was implemented to generate attenuation maps from NAC PET images. The model was preliminarily trained on approximately 60 paired NAC PET and CT images acquired on the LabPET8 scanner. The dataset consisted of mouse whole-body and body-without-head scans

obtained with two radiotracers: ^{18}F-FDG, and ^{11}C-acetate. Preliminary slice-level evaluation showed that the generated pseudo-CT images were visually consistent with the reference CT images and preserved the main anatomical structures in the evaluated regions. The generated pseudo-CT images achieved a structural similarity index measure (SSIM) of 0.991, a mean squared error (MSE) of 4.47×10^{-5} and a mean absolute error (MAE) of 8.51. These preliminary results suggest the feasibility of cDDPM-based pseudo-CT generation for preclinical PET attenuation correction, although full-volume validation and PET reconstruction studies using the generated attenuation maps are still required. Full results for more tracers and scanners will be presented at the conference.

Joint Self-Collimation Compton SPECT for Wide-Energy and High-SNR Imaging (#2)

Peize Li[1], Linxin Lei[1], Xingchun Zheng[1], Zhenlei Lyu[1], Rutao Yao[2], Tianyu Ma[1]

[1] Tsinghua University, Department of Engineering Physics, Beijing, China; [2] University at Buffalo SUNY, Department of Radiology, Jacobs School of Medicine & Biomedical Sciences, Buffalo, USA

Abstract

Mechanical collimators enforce a strict resolution-sensitivity trade-off, necessitate hardware exchanges for wide-energy imaging, and suffer from poor high-energy performance due to septal penetration. We propose Joint Self-Collimation Compton (JSCC) SPECT as a wide-energy solution using a multi-layer stochastic mosaic detector. JSCC integrates geometric constraints with Compton kinematics to screen pathways and suppress artifacts. Cylindrical-coordinate-based fast modeling accelerates volumetric reconstruction. Simulations using Hot-rod, Contrast, and Hoffman phantoms demonstrate that JSCC achieves a significantly superior signal-to-noise ratio compared to parallel-hole SPECT. At 511 keV, JSCC resolves 16-mm and 10-mm rods in 2-minute and 20-minute scans, outperforming the baseline (22-mm and 16-mm). At 140 keV, it resolves 9-mm rods in 30 seconds without hardware modification. These results demonstrate the potential of JSCC as a wide-energy, high-SNR SPECT imaging paradigm for next-generation molecular imaging and theranostic applications.

We acknowledge the Rising Faculty Science and Technology Acquisition and Retention (STARs) Program, The University of Texas System, for the generous support and the NIH National Institute of Biomedical Imaging and Bioengineering (grant R21EB037274-01A1) as funding agency.

Abstract

The growing integration of robotics in medical imaging applications [1], the maturation of high-resolution room temperature semiconductor detectors, and the push towards safe, cost-effective and easy-to-use imaging platforms [2], motivates the development of a robotic SPECT system designed to overcome the inherent limitations of traditional platforms. The high flexibility of the robot enables acquisition trajectories not attainable with standard gantry-based systems, practically implementing the concept of adaptive SPECT [3].

We propose a system based on a collaborative 7-degrees-of-freedom robot, a CZT detector panel, a custom-designed multi-pinhole tungsten collimator, a LiDAR sensor for environment awareness, and a 3D structured light camera for object localization and occupancy.

Inverse kinematics and Bidirectional Rapidly exploring Random Trees are used for determining the robot configurations and collision-free movement. Energy calibration of the detector shows a FWHM of 4.94 keV at 122 keV, and an energy range up to 380 keV, suitable for imaging of most clinical and theranostics radiotracers. Integration of a LiDAR sensor and a 3D structured light camera shows high precision in object detection ($AP_{0.5}$>0.90) and point cloud stitching via Eye-in-Hand calibration.

Noisy Jaszczak phantom simulations show that robot-enabled spherical acquisition outperforms standard cylindrical scanning, yielding better metrics at the minimum NRMSE iteration: NRMSE improved by 18%, the peak-to-valley ratio for the 6.4 mm rods increased of 55.3%, and the average contrast-to-noise ratio and contrast recovery coefficient increased by 5.1% and 5.3%, respectively, with maximum gains over 13% for the smallest sphere.

Abstract

For patients undergoing cardiotoxic cancer therapies, baseline cardiac function is assessed using echocardiography to calculate left ventricle ejection fractions (LVEFs). At many sites, this requires additional patient visits and could delay treatment as use of these therapies increases. We investigate whether LVEF can be automatically derived from routine ^{18}F-fluorodeoxyglucose (FDG) PET/CT scans acquired on a high-sensitivity Omni Legend scanner. Our retrospective study of FDG PET lymphoma scans (n=437) was organised into three complementary cohorts addressing gating validity, preliminary clinical comparison, and real-world applicability. In 5 electrocardiogram(ECG)-gated PET/CT scans, algorithm-generated triggers showed strong agreement with ECG triggers, with standard deviation trigger shift < 0.03. Of patients with ground truth echocardiograms (n=5), algorithm-derived LVEFs showed good agreement with echocardiography (mean absolute error = 5.1%), within the clinically accepted range for echocardiographic reporting variability (10%). Across the full dataset, sufficient myocardial uptake for heart localization and edge detection was observed in 153/437 cases (35.0%), while 207/437 (47.4%) lacked sufficient uptake despite successful algorithm execution. This cohort data suggests the potential for automatic LVEF estimation for one third of patients. Future work will investigate pipeline improvements such as refining the basal plane localisation to enable a LVEF estimation for a greater proportion of patients. Overall, these preliminary results indicate the potential for FDG PET derived LVEF with good ECG gating agreement and acceptable early agreement against echocardiographic reference values. Ongoing analysis of ground truth EFs will further evaluate classification of abnormal LVEF (< 50%) and establish myocardial uptake thresholds to guide clinical applicability.

Abstract

Compton scatter of gamma-rays within detector elements, denoted as inter-crystal scatter events, has been considered a resource for sensitivity improvement in PET imaging. The obstacle for their exploitation has been the resolution and contrast degradation due to inclusion of these events, related to the lack of knowledge of the first interaction position. We studied inter-crystal scatter events experimentally using a modular system based on single-end readout modules, also able to perform Compton polarimetry. Two modules comprising 16 x 16 GAGG:Ce scintillator matrices read out by silicon photomultipliers were mounted on a rotating gantry with 430 mm diameter. Two types of events were selected: (i) with a single pixel firing in one module and a two-pixel hit with forward Compton kinematics in the opposite module, and (ii) two-pixel Compton events in both modules with a pronounced polarization correlation. We imaged Ge-68 rod sources, and a NEMA NU-4 phantom with a Ga-68 solution. They results show that the statistics increases by 18 % using (i) and by an extra 8 % when adding (ii), compared to pure single-pixel events. At the same time, the inclusion of the selected inter inter-crystal scatter events has a marginal effect on image resolution (central field-of-view), shifting it from 2.5 +/- 0.1 mm (FWHM) for the single pixel events, to 2.7 +/- 0.2 mm (FWHM) for the combined sample, while the signal-to-noise and contrast-to-noise values are moderately increased. This validates the use of the inter-crystal scatter events for improved sensitivity and image quality in PET.

Abstract

Minimally-invasive radio-guided surgery requires simultaneous functional nuclear guidance and anatomical visualization to enable precise intraoperative localization of radiolabeled targets [1]. We propose a dual-modality imaging drop-in capsule designed for deployment through a standard 15-mm laparoscopic trocar. It consists of a 2-mm thick semiconductor detector with a sub-millimeter pixel pitch [2,3], a custom lofthole collimator embedded within a 3D-printed tungsten capsule, and two miniaturized stereoscopic micro-cameras.

Preliminary results show: real-time 3D depth maps validated against an ultrasonic distance sensor; a seamless 360° panoramic view stitched from sequential frames using cylindrical warping and multi-band Laplacian blending [4,5]; spectral localization of multiple isotopes ^{57}Co and ^{241}Am within a scattering biological medium; and a preliminary 2D co-registration overlaying the functional dataset onto the anatomical scene. We will present the system design and components, and discuss the steps towards a fully integrated prototype for laparoscopic radio-guided surgery.

Abstract

Lutetium-177 (^{177}Lu) is one of the most representative radionuclides in integrated nuclear medicine theranostics. To image ^{177}Lu, we have developed a full-ring, high-sensitivity cascade gamma photon coincidence imaging system. This work presents the system construction and preliminary performance evaluation.

The detector ring consists of 40 continuous $LaBr_3$ crystal modules arranged in 10 radial × 4 axial configuration (each 50 × 50 × 6 mm³). The inner diameter of the ring is 110 mm, with axial module spacing of 60 mm. Each crystal is coupled to four MPPC arrays and read out via PETsys FEM256 electronics, with three FEB/D boards and one DAQ for data acquisition. Both the ASICs and MPPCs are cooled by a water-cooling system, maintaining water at 8 °C and ASIC temperature below 20 °C.

The collimator assembly comprises 10 tungsten plates (26 × 128 × 8 mm³), each covering four axial detector modules. Plates are arranged alternately with pinholes and slits (1 mm), placed at a vertical distance of 36.5 mm from the ring center, creating an imaging field of Φ30 × 30 mm. The prototype hardware has been fully assembled and is capable of normal data acquisition.

Simulation results indicate a coincidence sensitivity of 2.97 × 10^{-5} at the central field of view, spatial resolution of ~1.7 mm, and hot cylindrical object resolution up to 1.2 mm. Preliminary experimental tests have validated the feasibility of the system. Ongoing optimization includes crystal position calibration, energy resolution improvement, and collimator geometry alignment. The full system performance evaluation is expected to be completed before the upcoming conference.

Abstract

Positron emission tomography and single photon computed emission tomography are widely used nuclear medicine modalities. These modalities provide information on physiological and metabolic functions by visualizing radiotracer distributions. However, they cannot obtain local information, such as intermolecular interactions, pH, and other microenvironmental factors. We have proposed and demonstrated a novel nuclear medicine imaging and quantum sensing method utilizing the characteristics of cascade radionuclides. For imaging, the coincidence detection of cascade gamma rays enables localization of the source position using directional detectors. For sensing, changes in angular correlation between cascade gamma rays provide local information, such as pH [1]. In our previous studies, angular distribution information was used as an indicator of angular correlation changes because the time resolution of measurement system of approximately 50 ns was insufficient for time-differential perturbed angular correlation analysis. In this study, we developed the improved time resolution of the measurement system using GFAG pixel scintillator detectors, originally designed 64-channel slew rate limited time-over-threshold integrated application specific intesgrated circuits, [2] and 62.5 ps sampling data acquisition systems [3]. The time-dependent perturbation factor exhibited pH-dependent decay behavior consistent with a previous study [4], with slower decay at low pH and faster decay at higher pH. In addition, ^{111}In-labeled OctreoScan showed different after-effect behavior from aqueous $^{111}InCl_3$ solutions, suggesting that time-differential analysis provides information beyond integrated angular distribution measurements. We will incorporate the time-differential perturbed angular correlation analysis into double-photon coincidence imaging and investigate its potential for nuclear medicine application.

Abstract

In matter, a positron annihilates with an electron into two photons through several mechanisms, including direct annihilation and the formation of positronium, a metastable bound state that exists as either para-positronium or ortho-positronium. Each channel has a characteristic lifetime, allowing their contributions to be distinguished in time. The two photons are predicted to be entangled in their polarizations [1], and recent measurements indicate that the degree of entanglement depends on the annihilation channel [2]. In particular, the ortho-positronium decay is sensitive to the local concentration of molecular oxygen, and can serve as a probe of tissue hypoxia in PET imaging [3]. The Jagiellonian Positron Emission Tomograph is a scanner built from plastic scintillators, in which 511 keV photons interact predominantly through Compton scattering [4]. The Compton scattering plane of each photon is correlated with its polarization. We measure annihilations of positrons emitted by a sodium-22 source embedded in porous polymer. Sodium-22 emits a positron accompanied by a 1274 keV prompt photon, which provides a time reference for the positron lifetime. The polarization correlation distribution of the annihilation photon pairs is consistent with quantum entanglement, between the limits for maximally entangled and classically separable states [2]. Selecting events by positron lifetime reveals distinct polarization correlation distributions for different annihilation channels. A detailed comparison will be presented at the conference. These results motivate quantum-informed PET imaging, with tissue hypoxia as a clinical biomarker.

Abstract

This research presents the development and first in-vivo demonstration of Positronium Ratio Imaging, a novel functional imaging technique that uses the three-photon to two-photon decay ratio of positronium. While conventional Positron Emission Tomography primarily maps radiopharmaceutical distribution, Positronium Ratio Imaging provides insights into the tissue microenvironment by exploiting the sensitivity of ortho-positronium to local oxygen levels and morphology. We characterized the system's geometric stability using a four-rod phantom with varying dimensions and evaluated the results against Monte Carlo simulations using the Geant4 toolkit. The phantom study identified a size-dependent uncertainty baseline of approximately twenty percent, primarily arising from detector sensitivity and geometric factors. Furthermore, we achieved the first in-vivo ratio imaging using a tumor-bearing mouse model administered with fluorine-18 fluorodeoxyglucose. Quantitative analysis revealed that the three-photon to two-photon ratio in brown adipose tissue was approximately two and a half times higher than in the heart and bladder. This significant contrast is consistent with theoretical trends derived from tissue-specific positronium lifetimes and far exceeds the established hardware-induced uncertainty. These findings validate the feasibility of using standard positron emitters for functional three-photon imaging without the need for specialized prompt-gamma emitters. Future work will focus on refining quantitative calculation methods, evaluating signal-to-noise ratios, and implementing hardware-specific calibrations to enhance absolute quantification. This technology lays a foundation for clinical applications such as the non-invasive visualization of tumor hypoxia and metabolic characterization of the tissue microenvironment, offering a breakthrough in functional molecular imaging.

Abstract

Positronium annihilation lifetime spectroscopy (PALS) has recently attracted considerable interest as a potentially sensitive tool for tissue characterization. In standard PALS experimental setups, at least two detectors are needed to provide start and stop signals for positron emission and annihilation creation. However, due to the isotropic nature of prompt-gamma emission, in a very significant fraction of events, both prompt and annihilation photons are detected in the same detector, resulting in a pileup event. In this work, we propose using these pile-up events to simplify o-Ps lifetime estimation workflows,
enabling estimation with a single detector. Using a 22Na source sample, we successfully measured the o-Ps lifetime using both standard coincidence PALS and the proposed approach with excellent agreement (1.88±0.04 and 1.90±0.07 ns). Measurements of o-Ps lifetime in an isopropanol-based liquid using 44Sc, as well as in ex-vivo biological samples from mice (liver and plasma) after a PET acquisition using 52Mn, were also obtained. These results demonstrate the feasibility of single-detector o-Ps measurement and open new lines of research, by facilitating the characterization of samples from PET studies.

Abstract

We present quantitative 4D PET imaging of photosynthate carbon transport and rhizosphere exudation in intact Phaseolus vulgaris plant–soil systems using the R-PET (Rhizo-PET) scanner with the ^{11}C radiotracer ($t_1/_2$ = 20.3 min). Across N = 6 plants, time–activity curves (TACs) extracted from 225 cross-pattern ROIs per dataset—spanning 3 roots × 3 axial depths × ±3 mm radial extent—reveal a reproducible source-to-sink carbon allocation hierarchy: upper root zones receive ≈50% of total plant carbon, while root 2 (primary taproot) dominates at 20.8 ± 6.3%. Time-to-peak (TTP) increases from 31.5±4.4 min (upper) to 48.0±13.1 min (lower root 2), corresponding to a phloem transport velocity of ≈2.4 mm min^{-1}. Rhizosphere carbon exudation follows an exponential decay AUC(r) = A e^{-kr} with k = 0.10–0.20 mm^{-1}, placing the active deposition zone within 4–14 mm of the root surface—the first spatially resolved 3D+t measurement of this process in intact soil.

Investigating an Optical Approach for Microliter-Scale Droplet Geometry Correction in Radioactivity Quantification (#3086)

Shawn Shin, Robert Carmichael, Weiting Deng, Juan Alexander Leal Doblado, David Prout, Robert Michael van Dam, Arion Chatziioannou

University of California, Los Angeles, Department of Molecular and Medical Pharmacology, Crump Institute for Molecular Imaging, Los Angeles, USA

Abstract

Positron-labeled tracers are powerful tools for studying diseases and developing new therapeutics, yet conventional radiochemistry platforms are complex, costly, and low-throughput, making PET tracer development slow and resource-intensive. To address this bottleneck, we are constructing a high-throughput radiochemistry system that will enable multiple radiosyntheses to be performed in parallel. A key challenge is accurately quantifying radioactivity in each microliter-scale droplet throughout the radiosynthesis process. While plastic scintillators and an overhead CMOS camera offer a compact detection approach, the scintillation signal is confounded by variations in droplet volume and geometry. Geometry correction is therefore critical for reliable activity quantification.

We investigated an optical approach to infer droplet geometry by leveraging its optical reflective and refractive properties. Droplets were illuminated with a ring light mounted around the camera lens, and we sought to infer their geometries from the resulting optical features. Experimental images were acquired from evaporating water droplets on a Teflon-coated silicon chip, and ray-tracing simulations were performed on droplet models reconstructed from side-profile images. Both revealed two distinct features from independent optical processes: a mirror reflection effect and a lensing magnification effect. These varied systematically with droplet volume, suggesting they encode geometry information and may provide complementary information for inference.

These preliminary findings support the feasibility of this optical method for geometry estimation and radioactivity quantification correction. The approach adds minimal complexity to the existing system and is well-suited for integration into a compact radiochemistry robot. Future work will focus on refining droplet shape models, extending the method to off-axis droplets, and evaluating image-analysis approaches for robust geometry inference.

How well do we know non-collinearity in PET? A simulation and a new analysis of past and recent experiments (#2250)

Andrea Espinosa[1], Pablo Galve[2,1], Luis M. Fraile[1,3], Joaquín López Herraiz[1], **Jose M. Udias**[1]

[1] Universidad Complutense de Madrid, Grupo de Física Nuclear, EMFTEL & IPARCOS, Madrid, Spain; [2] Spanish National Research Council (CSIC), Institute for Physical and Information Technologies "Leonardo Torres Quevedo", ITEFI, Madrid, Spain; [3] CERN, ISOLDE, EP Department, Geneva, Switzerland

Abstract

Positron-electron **non-collinearity** of the 511 keV annihilation-photon has been derived from several experiments. In the one hand, of the (anti-)correlation between Doppler broadening induced by the transverse momentum component of the annihilating pair, and photon non-collinearity. Direct non-colinearity measurements with pin-hole or slits provide also noncolinearity information. In the past, discrepancies in the non-collinearity derived from both kinds of experiments have arised, and the non-collinearity value generally accepted has been solely derived from Doppler broadening experiments. To better understand non-collinearity, we review the correlation between the kinematics of the initial electron-positron pair and the emitted non-collinear photon. We then use a detailed 3D simulation of the kinematics annihilation of the e-e+ pair, including the motion of the initial pair of leptons, which in turns introduces the energy broadening of the 511 keV peak, and the non-collinearity of the final photons, linked to the underlying electron kinetic-energy distribution. To this end, initial electron kinetic energies are sampled from a semi-Gaussian distribution, while initial electron directions are sampled isotropically. We fit the initial kinetic energy distribution of the electron-positron pairs to reproduce, after the detailed 3D simulation, the observables in each kind of experiments, either Doppler broadening or actual non-collinearity in slit experiments. We find that the same initial electron kinetic energy distribution explains both Doppler broadening and accurate slit experiments in water at room temperature. Finally, we compare our extraction for non-collinearity distribution, and found it similar to the one presented by Tuoissant et al in 2024, confirming that non-collinearity is being underestimated in most MC simulations of PET scanners.

Abstract

Positron Annihilation Lifetime has previously been demonstrated to provide useful information in PET imaging. Due to the fact that the annihilation time depends on the tissue where the annihilation occurs, to disentangle the different times for heterogeneous tumors is extremely challenging. Geant4, the toolkit for the simulation of the passage of particles through matter developed at CERN, has been shown to be a good candidate for medical physics simulations. The main drawback is that Geant4 code does not include Positron Annihilation Lifetime information in the source code. The IRIS group at IFIC (Valencia) has developed PAL-G4, an unofficial version of Geant4 that introduces the possibility to add measured Positron Annihilation Lifetimes for different materials in order to be able to simulate realistic scenarios. In order to test the PAL-G4 code, the BrainPET-7T insert for magnetic resonance at the PET-physics group at the Forschungszentrum Jülich GmbH was simulated. Two cases were simulated, one in which the annihilation took place in a homogeneous medium, and another in a heterogeneous medium. The simulation results fit the expected behavior in terms of the detected annihilation times in both cases, thereby showing the suitability of using PAL-G4 for real case studies. Further measurements of annihilation times for various sources and tissues of interest in medical applications will be measured with the BrainPET-7T and used as input parameters for the PAL-G4 code. The simulations results will be compared with the measured data in all cases.

Abstract

Accurate system response modeling is essential for quantitative SPECT, but system response functions (SRFs) generated from nominal collimator geometry can deviate from the response of the actual system due to aperture imperfections, mechanical misalignment, and septal penetration. This mismatch is especially significant for a non-conventional aperture. We propose a data-driven SRF modeling method that reconstructs a directional penetration map from sparse point-source scans. In the proposed aperture-domain representation, each source-detector measurement is indexed by its aperture crossing position and ray direction, allowing measurements from different source locations and detector pixels to be pooled into a shared position-direction map. The map represents the effective material path length, which is estimated by maximum likelihood under a Poisson model with latent detector-depth sublayers, and the resulting problem is solved using an expectation-maximization (EM) algorithm. SRFs for arbitrary source locations can then be generated through the ray-tracing method by combining geometric factors with the learned path length and the photon-energy-dependent attenuation coefficient. Preliminary Geant4 validation using a 16-aperture micro-ring CZT-based SPECT model with controlled collimator tilting demonstrates that scan-based SRFs recover aperture-level response features missed by nominal-design SRFs and agree more closely with the ground-truth tilted-collimator response at non-scanned source positions. Experimental validation on the clinical AlphaSPECT system and image-domain evaluation will be presented at the conference.

Wasserstein Pullback Metric for Intrinsic Difficulty of Scintillation Detector Inverse Problems (#2265)

Sangjin Bae[1,2], Jae Sung Lee[1,3]

[1] Seoul National University Graduate School, Interdisciplinary Program in Bioengineering, Seoul, South Korea; [2] Seoul National University Graduate School, Integrated Major in Innovative Medical Science, Seoul, South Korea; [3] Seoul National University Hospital, Department of Nuclear Medicine, Seoul, South Korea

Abstract

Scintillation detector inverse problems are limited by how sensitively photon distributions change with interaction or detector conditions. We propose a likelihood-free Wasserstein-geometric framework for quantifying this distributional sensitivity using a pretrained generative model for scintillation photon transport. By representing conditional photon distributions as pushforwards of a latent distribution, the Jacobian of the transport map induces a Wasserstein pullback metric on the condition space. We use the trace of this metric as a local sensitivity measure and its detector-level average as the expected distributional sensitivity (EDS). The proposed sensitivity captures DOI and crystal-dependent timing trends, correlates monotonically with interaction localization error across crystal dimensions (Spearman ρ=-0.88 for rough Teflon and -0.90 for polished ESR), and supports differentiable detector optimization. These results suggest that Wasserstein sensitivity can provide an estimator-independent measure of inverse-problem difficulty and a tool for detector characterization and optimization.

Abstract

Mechanical detector misalignments in positron emission tomography (PET) scanners, caused by manufacturing tolerances as well as mechanical and thermal stress, lead to inaccurate line of response (LOR) positioning and consequently degrade image quality and quantitative accuracy. Existing calibration methods typically rely on dedicated measurements with known tracer distributions, requiring either calibration phantoms or precisely positioned point sources. These procedures are time-consuming, operationally demanding, and difficult to integrate into PET-MRI systems due to magnetic field constraints. This work proposes an unsupervised detector alignment calibration method that estimates detector misalignments from point-source measurements with unknown source positions. The proposed approach estimates source locations using an iterative likelihood-based optimization and derives detector alignment parameters from the resulting LOR geometry, eliminating the need for externally calibrated source positioning. The method is evaluated on a simulated PET scanner and achieves translational and rotational alignment accuracies of 0.95mm and 0.41°, respectively, while the source positions are recovered with an accuracy of 0.61mm using only 3×10^5 LORs. By avoiding specialized calibration hardware and requiring only limited acquisition data, the proposed method enables rapid, flexible, and easily deployable PET calibration. Its low operational complexity and short acquisition time make it particularly promising for routine clinical recalibration and for hybrid imaging systems such as PET-MRI.

Abstract

Positronium-based imaging [1-3] requires accurate Monte Carlo modelling of positronium decay in matter. Existing implementations in the Geant4 Application for Tomographic Emission simulation framework [4-5] are limited to at most two annihilation channels, which is insufficient to represent the multi-component lifetime structures observed in biological tissues and complex materials. We present a new modular positronium decay source model implemented in both GATE versions 9.4 and 10 [5], enabling the simultaneous definition of an arbitrary number of decay channels. Each channel is independently characterised by its mean lifetime, branching fraction, annihilation multiplicity into two or three photons, and optional prompt photon emission, as required for radionuclides such as scandium-44, gallium-68, and iodine-124. The model is validated through analytical and numerical benchmarks. Branching fractions are correctly reproduced within statistical uncertainties across all tested configurations. Practical applicability is demonstrated through simulations of a NEMA Image Quality phantom filled with tissue-mimicking positronium sources representing water, fat, muscle, and bone. The implementation is fully compatible with standard simulation workflows, providing the community with the first general-purpose, multi-channel positronium decay model integrated into a widely adopted medical physics simulation framework.

Abstract

Carbon-ion radiotherapy enables highly precise tumor treatment, particularly for locations near critical structures such as the brainstem or spinal cord. However, the focused dose distributions that make this modality effective also increase its sensitivity to variations in the beam path. Consequently, accurate monitoring and control of the dose distribution in the patient are essential. Despite this clinical need, radiation-free monitoring approaches are scarce. In order to investigate use of secondary ions for this purpose, we compare measured ion distributions across treatment fractions. For this approach, a contactless detection system for secondary-ion tracking was developed and clinically implemented at the Heidelberg Ion-Beam Therapy Facility (HIT), Germany. The system enables tracking of individual secondary-ions with high spatial and temporal resolution.

The performance of the developed monitoring approach is currently being assessed within the clinical study “InViMo.” To date, more than 100 patient measurements have been acquired. For the majority of patients, the measured data showed consistency across treatment fractions. However, pronounced inter-fractional variations were observed in several cases. These signals demonstrated clear spatial correlation with the anatomical ground truth derived from CT imaging, including challenging cases involving deep-seated tumors. In addition, the system enabled a worldwide first measurement of a patient treated with helium ions, a promising modality for several pediatric tumor indications. Considerable amount of secondary ion tracks was recorded.

Our results demonstrate that the proposed method can detect clinically relevant anatomical changes in treated patients with high sensitivity and accurate spatial localization.

Abstract

Objective: Online range monitoring is critically important in proton therapy, as range uncertainties arising from patient positioning, anatomical variations, and range calculation algorithms remain a major limitation in precise dose delivery. Prompt gamma-ray imaging (PGI) offers a promising solution for real-time range verification due to the ultra-fast emission of prompt gamma rays. However, for the most advanced dose delivery technique—pencil beam scanning—proton beams are delivered in a three-dimensional (3D) lattice, necessitating 3D online monitoring systems capable of spot-by-spot range and dose verification within a single acquisition.

Approach: In this study, a dual-head 3D PGI system based on multi-slit collimated gamma-ray cameras was evaluated for proton beams delivered to 3D lattices. Experiments were conducted in a clinical proton therapy treatment room using a proton beam of typical therapeutic energy incident on a polymethyl methacrylate (PMMA) phantom. The precision and accuracy of both range verification and beam spot positioning were systematically assessed.

Main results: At a typical low proton count level of 1×10^8 protons per scanning spot, the system achieved accuracy and precision better than 1.5 mm for both range verification and beam spot positioning. At proton counts of 3×10^8 or higher, both metrics improved to sub-millimeter levels (<1 mm).

Significance: These findings demonstrate that the dual-head 3D PGI system is capable of high-precision, spot-by-spot range and beam spot verification even at low proton counts, highlighting its potential for effective online in vivo monitoring in 3D pencil beam scanning proton therapy.

This work was supported by the REALPATH project (Italian MUR), grant n. FISA-2022-00779

Abstract

Hadrontherapy is a kind of radiation therapy that delivers highly localized radiation doses to treat tumors spearing healthy tissues. In this context, Prompt Gamma Imaging (PGI) is a promising technique towards real-time monitoring of the particle beam range, thereby enhancing both treatment precision and patient safety. The REALPATH project aims to develop a compact range verification system based on passive collimation and a pixelated gamma camera. The detector utilizes LYSO scintillator crystals coupled to silicon photomultipliers (SiPMs), organized into 64- channel base units that scale up to a 512-channel instrument with a 20 × 10 cm² footprint. The primary objective of this project is to overcome the physical and operational barriers that currently prevent PGI systems from being used during standard treatment workflows. For this reason, the detector and electronics are engineered to maximize detection efficiency, minime acquisition dead time, while reducing the footprint of the system. A novel ”inverted” collimator design significantly reduces the overall instrument weight and allows the camera to be rigidly fixed beneath the patient couch. The experimental results obtained from measurement campaigns at CNAO facility in Pavia, Italy are also reported.

Abstract

Proton therapy provides highly conformal dose delivery and the integration of in-vivo range verification can further enhance treatment safety and efficacy by serving as a trigger for intervention and by decreasing safety margins [1]. The NOVO collaboration [2] investigates a novel hybrid detector concept that combines prompt gamma ray and fast neutron imaging in a compact organic-scintillator-based system to improve proton range verification. This dual-particle approach offers complementary particle information and thus improved localisation capabilities [3]. For the first time, the NOVO detector was operated at a clinical proton beam at the OncoRay proton therapy facility in Dresden, Germany [4]. The system's detection performance and imaging capability were investigated by irradiating different phantoms with numerous proton energies and beam currents and by varying the phantoms' position and compositions. The detector array demonstrated stable performance under clinically relevant mixed-field and high-rate conditions and achieved reliable neutron–photon discrimination. Furthermore, images could be reconstructed which provide the first experimental validation of the combined n/gamma approach in proton therapy and highlight its strong potential as a future real-time range verification technique.

Abstract

Biological washout, traditionally considered a source of error in range-verification PET in particle therapy, is now emerging as a potential new biomarker for tumor diagnosis. At QST, proof-of-concept studies using animal irradiation at HIMAC demonstrated a correlation between hypoxia PET maps and washout rate maps derived from range-verification PET. However, due to facility limitations, including radioisotope regulation constraints, hypoxia PET had to be performed on the day following irradiation. As a result, confounding factors such as tumor growth and delayed irradiation effects could not be fully excluded. In contrast, LMU has developed the Small Animal Proton Irradiator for Research in Molecular Image-Guided Radiation Oncology (SIRMIO) that includes an in-beam PET scanner, and conducted experiments at DCPT, which offers close integration with a nuclear medicine division. Leveraging this environment, we designed an experimental protocol to perform both proton range-verification PET (irradiation-PET) and hypoxia PET (FAZA-PET) on the same platform with a shortened interval using the SIRMIO system at DCPT. Considering that the activity level in range-verification PET is much lower than that in FAZA-PET, ^{18}F-FAZA administration was performed after the irradiation-PET. The time interval between the two PET scans was reduced to < 4 hours, which is sufficient for FAZA uptake while minimizing biological changes in the tumor. The first proof-of-concept experiment was conducted using mouse models bearing SCCVII tumors. Mouse was positioned in a custom-made holder, and co-registration was ensured by on-board μCBCT. A low washout rate in hypoxic areas was observed, which may be explained by poor blood perfusion. Correlation to in-beam PET data will be analyzed and reported.

Beyond short-lived positron emitters: feasibility of ^{18}F detection for range verification in carbon ion therapy (#1521)

Akram Hamato[1], Chie Toramatsu[1], Hidekatsu Wakizaka[1], Hideaki Tashima[1], Yuma Iwao[1], Han Gyu Kang[1], Go Akamatsu[1], Katia Parodi[2], Taiga Yamaya[1]

Abstract

In carbon ion therapy, positron emission tomography (PET) is one of the most investigated methods for range verification that relies on short half-life β^+ emitters such as ^{11}C and ^{15}O. Consequently, in-beam PET or off-beam PET performed immediately after irradiation have been considered mandatory, and little attention has been paid to the existence of longer-lived β^+ emitters than ^{11}C. With a recent increase in PET system sensitivity, delayed acquisitions targeting longer-lived β^+ emitters have become increasingly feasible. In this study, therefore, we focused on the feasibility of off-beam detection of an irradiation-induced ^{18}F component for range verification in carbon ion therapy. Monte Carlo simulations were first performed to estimate the yield of ^{18}F and the other most important β^+ emitters induced in a polymethyl methacrylate (PMMA) phantom irradiated by carbon ion beams. The yield of produced ^{18}F was one-eighth that of the ^{11}C, and the shifts of the dose peak and PET peak were 1.5 mm and 0.5 mm for in- and off-beam PET, respectively. To validate the simulation results, a PMMA phantom and a live tumor-bearing rat model were irradiated with a ^{12}C ion beam of 290 MeV/u at the carbon therapy facility of the Heavy Ion Medical Accelerator in Chiba (HIMAC) to evaluate ^{18}F production in both simplified and biologically relevant environments. One hour after irradiation, PET scans were carried out for 30 min for both the phantom and the rat. Time-activity curves (TACs) were extracted from the PET images, and they showed the presence and detectability of ^{18}F. A measured activity profile was obtained from the off-beam PET image of the phantom and compared with the measured dose. The dose peak and PET peak positions were matched, which is consistent with submillimeter (0.5 mm) shift of the peaks for off-beam PET predicted from the simulation. Our results demonstrate the feasibility of ^{18}F for range verification in carbon ion therapy using off-beam PET.

Abstract

Kernelized expectation maximization (KEM) has emerged as an effective and practical approach for improving image quality in emission tomographic reconstruction by incorporating high-quality prior information into the iterative reconstruction process. In conventional KEM, the kernel matrix is derived from a prior image and remains fixed throughout reconstruction. This may result in artifacts when the prior image and target emission data are not perfectly matched, especially in cross-modality or cross-scanner settings, such as MR-guided PET reconstruction and PET-guided SPECT reconstruction in theranostic imaging. In those settings, differences in scanner characteristics, acquisition time points, or tracer distributions may cause mismatch between the prior image and the target emission data. In this work, we propose a steerable kernel reconstruction framework that adapts the prior-derived kernel representation according to the measured data. The proposed method dynamically updates the kernel matrix during reconstruction to improve consistency with the measured data. We evaluate the proposed method on 2D brain phantom data for MR-guided PET reconstruction and on 2D thorax phantom data for PET-guided SPECT reconstruction in a theranostic setting. Experimental results demonstrate that the proposed steerable kernel method mitigates mismatch-induced artifacts and achieves improved reconstruction fidelity compared with conventional fixed-kernel approaches. These findings suggest that adaptive kernel steering offers a promising direction for robust prior-guided emission tomography reconstruction under realistic mismatch conditions.

Abstract

PET image quality is affected by limited-count statistics and the ill-posed nature of tomographic image reconstruction. Deep learning methods have shown promise for improving PET image quality. However, most existing models have primarily been developed and validated using ^{18}F-FDG datasets. The generalizability of ^{18}F-FDG- trained models to less common radiotracers, particularly non-^{18}F tracers with distinct biodistributions and physical properties, has not been well demonstrated. As the clinical and research use of diverse PET tracers continues to expand, there is a growing need for unified deep learning reconstruction methods capable of generalizing across tracers. We previously developed a pretrained deep kernel model using a large-scale ^{18}F-FDG total-body PET dataset and demonstrated its feasibility for tomographic image reconstruction in static PET imaging by using a single-frame MLEM image as the image prior. Unlike post-reconstruction denoising methods that learn tracer-specific activity distributions and directly output images, the deep kernel method learns to construct a kernel matrix that reflects spatial correlations, making it potentially transferable across tracers. In this work, we extend the deep kernel pretraining by incorporating additional ^{18}F-FDG data and then investigate whether the ^{18}F-FDG-trained model can be directly applied to other non-^{18}F tracers without any tracer-specific training or fine-tuning. The proposed method was evaluated on fourteen ^{68}Ga-DOTATATE scans acquired with the uEXPLORER total-body scanner and compared against a state-of-the-art deep-learning denoising model that is also trained on ^{18}F-FDG total-body datasets. Results demonstrate that the proposed method significantly reduces image noise and achieves improved lesion quantitative accuracy. This work demonstrates the feasibility of cross-tracer PET reconstruction using an ^{18}F-FDG-trained deep kernel model, supporting future evaluation in larger multi-tracer datasets.

Abstract

Numerous AI-based solutions to PET image reconstruction, an ill-posed inverse problem, have been implemented to enhance image quality or convergence speed, yet most suffer from reliance on high-quality paired dataset and lack of robustness. As an emerging methodology, implicit neural representations (INRs) demonstrate tremendous potential in continuous modelling of spatial distribution. However, the existing INR-based PET reconstruction methods generally suffer from loss of information due to compression in sinograms they utilise as input, and do not include corrections for noise caused by the physical factors like attenuation and normalisation. In this work, we present a self-supervised PET reconstruction method based on neural radiance fields (NeRFs), a special type of INR with list-mode coincidences as input, where sensitivity is incorporated as both the weight for sampling points along each LOR and combined corrections for attenuation and normalisation. LORs with no recorded coincidences function as data-driven regularisation and are augmented as part of the input. Results using simulated and experimental data show that our proposed method can achieve excellent image quality and improved contrast, and outperform conventional iterative algorithms and other AI approaches, particularly in recovering fine details in small hot regions.

Abstract

Dynamic Positron Emission Tomography (PET) imaging is an essential tool for research in neurodegenerative diseases through the modeling of tracer kinetics.

However, achieving ultra-high spatial resolution in PET systems tends to reduce their overall geometric sensitivity. This leads to a possible compromise between dynamic frame duration, spatial resolution, and noise.

This study presents the application of a non-negative low-rank-constrained reconstruction method tailored for the ultra-high-resolution SAVANT scanner.

Traditional algorithms reconstruct PET images frame-by-frame without taking into account the natural spatiotemporal correlations within the data. This redundancy is leveraged by this method to reconstruct all the dynamic frames simultaneously.

The method alternates between updating a matrix representing the spatial distribution for each temporal basis, and updating a matrix representing the translation from temporal bases to frame.

In order to accommodate for the large memory and computational requirements associated with the SAVANT, we extended the nonnegative low-rank model to support list-mode data and optimized its implementation through Graphical Processing Unit (GPU) acceleration.

In vivo evaluations using a dynamic [18F]DG scan demonstrate a visible improvement in image quality when using the proposed method compared to the conventional frame-by-frame MLEM algorithm. The low-rank constraint allows to preserve greater detail and shows sharper anatomical structures, which better showcases the high resolution of the SAVANT system.

Abstract

X-ray scattering tensor tomography aims to recover orientation-dependent microstructural information beyond scalar attenuation or scalar dark-field CT. For quantitative reconstruction, however, an aquisition trajectory satisfying Tuy's condition should also provide enough independent angular sensitivity for the tensor model being reconstructed. We formulate this requirement as a generalized Tuy-type completeness condition for scattering tensor tomography, linking conventional geometric visibility with tensor sensitivity. This analysis shows that the former 15-component model is intrinsically incomplete: under each plane, only 12 independent tensor modes can be probed, so arbitrary 15-component fields require additional prior assumptions. In contrast, the reduced 6-component model satisfies the planar completeness requirement under sufficient angular coverage. Planar singular-value tests confirm both the 12-mode limit and the full rank of the reduced model, providing practical criteria for tensor-model selection and aquisition trajectory design and optimization.

Abstract

Single-photon emission computed tomography (SPECT) reconstruction is an ill-posed inverse problem, and standard clinical methods typically provide a single reconstructed image without an explicit characterization of uncertainty. In this work, we adopt a stochastic reconstruction approach based on Hamiltonian Monte Carlo (HMC), which generates an ensemble of radiotracer distributions consistent with the measured projection data and the assumed forward model. Rather than relying solely on the reconstructed mean image, this formulation enables both uncertainty-aware evaluation of conventional measures and the construction of new descriptors derived from ensemble variability. We investigate whether such ensemble-derived features can provide additional diagnostic information for DATSCAN SPECT analysis, complementing standard metrics such as striatal binding ratios (SBR). We show that normalized fluctuation measures extracted from the HMC ensemble exhibit distinct behavior between control and Parkinson's disease cases. These findings suggest that the stochastic reconstruction framework may provide additional diagnostic information and enhance the diagnostic capabilities of SPECT.

Monte Carlo–based reconstruction in Ac-225 SPECT: impact on image quality, quantitative accuracy, and computational burden. (#1164)

Chenguang Li[1,2], Pedro Esquinas[1,3], James Fowler[1,2], Xinchi Hou[3], Arman Rahmim[1,2], Carlos Uribe[2,3]

[1] The University of British Columbia, Department of Physics & Astronomy, Vancouver, Canada; [2] BC Cancer Research Institute, Department of Basic & Translational Research, Vancouver, Canada; [3] BC Cancer, Department of Molecular Imaging & Therapy, Vancouver, Canada; [4] University of British Columbia, Department of Radiology, Vancouver, Canada

Abstract

Purpose: Quantitative ^{225}Ac SPECT is challenging because of low counts, complex emissions, scatter, and septal penetration[1]. This study developed and evaluated a Monte Carlo (MC)-based reconstruction framework for ^{225}Ac SPECT, focusing on image quality, quantitative accuracy, and computational cost.

Methods: SIMIND was used as an MC forward-projector for a vendor-specific SPECT system with a high-energy collimator, while an analytical back-projector was retained to improve efficiency[2]. Unlike conventional MLEM with TEW scatter correction, the MC model incorporated patient scatter, collimator penetration/scatter, detector backscatter, and system response. Performance was evaluated using both simulated and experimental phantom data. The simulated phantom contained 20, 40, and 72 mm spheres, and the experimental phantom contained a 60 mm sphere, both with a 10:1 sphere-to-background activity ratio. Reconstructions used a 218 keV photopeak with a 20% window and were assessed using the recovery coefficient(RC) and contrast recovery coefficient(CRC).

Results: In simulations, MC reconstruction improved contrast recovery and reduced scatter and septal-penetration artifacts. At 25 iterations, mean CRCs for the 72, 40, and 20 mm spheres were 90.1%, 61.3%, and 21.9%, compared with 45.4%, 29.1%, and 9.4% for conventional reconstruction. MC reconstruction directly estimated activity in MBq and achieved RCs of 90.2% and 94.5% for the 72 and 40 mm spheres. Experimental results showed consistent improvement, with MC reconstruction more than doubling CRC at 25 iterations (75.4% vs. 29.2%) and achieving an RC of 88.5% for the 60 mm sphere. Reducing photon histories from 600 to 30 million per projection preserved accuracy for the 72 mm sphere while reducing runtime from 53 to 3.1 min per iteration.

Conclusion: MC-based reconstruction substantially improves image quality and quantitative accuracy for ^{225}Ac SPECT and may support more reliable post-therapy imaging and dosimetry.

Sparse-View ^{177}Lu SPECT Reconstruction for Pre-Treatment Dosimetry using Gaussian Mixtures (#2004)

Hyun Ji Lee[1,2], Sangjin Bae[1,2], Jae Sung Lee[1,2]

[1] Seoul National University Graduate School, Interdisciplinary Program in Bioengineering, Seoul, South Korea; [2] Seoul National University Graduate School, Integrated Major in Innovative Medical Science, Seoul, South Korea; [3] Brightonix Imaging Inc., Seoul, South Korea

Abstract

Pre-treatment dosimetry for ^{177}Lu-DOTATATE therapy requires accurate reconstruction from low-dose sparse-view SPECT imaging, which remains challenging due to severe noise and limited projection information. We propose a Gaussian Mixture Model (GMM)-based reconstruction framework with projection-domain optimization for sparse-view ^{177}Lu SPECT imaging. Experimental results on multi-timepoint ^{177}Lu-DOTATATE SPECT datasets demonstrated competitive reconstruction and dosimetry performance with substantially faster optimization under sparse-view conditions.

Abstract

This study proposes a Noise-Aware Brownian Bridge Diffusion Model (NA-BBDM) for low-dose positron emission tomography (PET) denoising. The proposed NA-BBDM models a conditional diffusion path between paired low- and full-dose PET images and incorporates the estimated noise level from the input image into the network. The noise level is estimated from the variance of the residual between the low-dose image and a Gaussian-smoothed version. The diffusion path uses a parabolic variance schedule with zero variance at both endpoints (i.e., low- and full-dose images), parameterized by peak variance and number of diffusion steps. Both are treated as noise-dependent hyperparameters and optimized through grid search. Training data consisted of 25 ^{18}F-FDG datasets acquired on the PennPET Explorer and subsampled to emulate dose levels from 1/5 to 1/300 of total counts. Performance was compared with a U-Net and evaluated on independent ^{18}F-FDG and unseen ^{11}C-carfentanil (CFN) datasets. The NA-BBDM produced images with reduced noise speckles (still present with the U-Net) and better-preserved high-uptake regions at ultra-low-dose levels. Quantitatively, the NA-BBDM also achieved lower SUV variability and mean squared error for ^{11}C-CFN, especially below 1/60th dose. Our results suggest that the NA-BBDM provides a robust framework for ultra-low-dose and cross-tracer PET denoising.

N2N-DiffPET: Self-supervised Diffusion for Low-dose PET Image Denoising (#2281)

Kailong Fan[2,1], Yichen Wu[1], Quanzheng Li[1], Huafeng Liu[2], Ning Guo[1]

[1] Massachusetts General Hospital and Harvard Medical School, Department of Radiology, Boston, USA; [2] Zhejiang University, Department of Optical Engineering, Hangzhou, China

Abstract

Low-dose positron emission tomography (PET) imaging can reduce radiation exposure and shorten acquisition time, but reduced photon counts introduce strong count-dependent noise and degrade quantitative reliability. Supervised deep learning methods usually require paired low-dose and normal-dose PET images, which are difficult to acquire in clinical practice. We propose N2N-DiffPET, a self-supervised diffusion framework for low-dose PET denoising without normal-dose supervision. Inspired by recent self-supervised diffusion MRI denoising, N2N-DiffPET adapts iterative diffusion refinement to PET using paired noisy PET observations generated from independent low-dose measurements by event splitting or Poisson resampling. To better model PET noise, N2N-DiffPET constructs a fusion trajectory between the paired noisy PET images and perturbs it using pair-derived PET noise rather than synthetic Gaussian noise. Co-registered MRI is incorporated as an anatomical condition to improve structural preservation. During inference, bidirectional deterministic denoising is performed, and the two directional outputs are averaged to reduce directional bias. Normal-dose PET images are not used for training and are only used for evaluation. Experiments on BrainWeb-based PET/MR simulation data show that N2N-DiffPET suppresses noise while preserving anatomical structures and regional uptake, outperforming conventional denoising methods and self-supervised baselines in visual quality and quantitative metrics.

Multi-Dose PET Image Denoising using Consistency Flow Matching

(#1864)

Joo Hyun Lee[1,2], Sangjin Bae[1,2], Jae Sung Lee[3,4]

[1] Seoul National University, Interdisciplinary Program in Bioengineering, Seoul, South Korea; [2] Seoul National University, Integrated Major in Innovative Medical Science, Seoul, South Korea; [3] Seoul National University, Department of Nuclear Medicine, Seoul, South Korea; [4] Brightonix Imaging Inc., Seoul, South Korea

Abstract

Low-dose PET reduces patient radiation burden by decreasing injected radiotracer dose or scan duration, but the resulting reduction in photon counts introduces statistical noise that degrades diagnostic image quality. Most deep learning denoising methods are trained at a single fixed dose reduction factor and do not generalize to unseen dose levels. We propose Consistency Flow Matching (CFM), a multi-dose denoising framework that augments flow matching with a cross-dose consistency regularization. During training, pairs of low-dose images at two different dose reduction factors are jointly processed, and a consistency loss enforces agreement between their predicted normal-dose outputs, promoting a dose-invariant flow field. Dose conditioning is achieved through Spatial Feature-wise Linear Modulation with a log-sinusoidal dose embedding. Experiments on the UltraLow-Dose PET Challenge dataset show that CFM improves perceptual image quality and out-of-distribution generalization over standard flow matching, confirming the benefit of cross-dose consistency regularization.

High-Temporal-Resolution Data-Driven Respiratory Motion Estimation in Cardiac PET Imaging (#1890)

Hongrong Wei, Chen Sun, Zhiheng Feng, Yue Li, Duo Zhang, Qing Ye, Yihuan Lu

United Imaging Healthcare, Shanghai, China

Abstract

Cardiac PET is widely used for myocardial perfusion imaging and viability assessment, both of which require high image quality and quantitative accuracy. In free-breathing acquisitions, respiratory motion can induce cardiac displacement, particularly along the superior-inferior (SI, z-axis) direction, leading to image blurring, attenuation-emission mismatch, and quantitative bias. Reliable estimation of this translation is therefore essential for effective motion correction. In this work, we propose COD-S (Centroid of Distribution-Scaled), a data-driven method to estimate respiratory-induced SI cardiac translation in cardiac PET. COD-S integrates the high sensitivity and high temporal resolution of COD analysis with the physically scaled displacement provided by image registration. Specifically, the respiratory motion trajectory is decomposed into waveform and amplitude components, where the waveform is derived from COD and the amplitude are calibrated using registration-based estimates. This produces a high-temporal-resolution and physically interpretable cardiac translation trajectory without external respiratory hardware, providing a practical input for motion correction in cardiac PET.

Spatial-variant fast non-linear energy calibration for a high resolution SSLE pixelated PET detector (#3118)

Lidia Jiménez Algarra[1], Víctor Sánchez Tembleque[1], Luis Batres Mongil[1], David Perez-Benito[1], Juan J. Vaquero López[1,2]

[1] Departamento de Bioingeniería, Universidad Carlos III de Madrid, Madrid, Spain, Departamento de Bioingeniería, Leganés, Spain; [2] Instituto de Investigación Sanitaria Gregorio Marañón, Madrid, Spain, Madrid, Spain

Abstract

High-resolution PET detectors require position dependent energy calibration due to the spatial variability of their optical response. This work addresses that challenge for a novel hexagonal LYSO detector structured by subsurface laser engraving (SSLE) with a double honeycomb displaced crystal array, coupled to a custom 61-channel hexagonal SiPM. This design provides two depth-of-interaction (DOI) layers as well as a high-granularity for event's positioning. We first present a DOI separation method based on a dispersion metric computed from the per-channel light distribution, enabling crystal pixel specific calibration for each layer independently. After precise vertex identification, energy calibration is then performed per crystal pixel by fitting four reference points: the 202 and 307 keV intrinsic 176Lu peaks and the 511 and 1275 keV peaks from a 22Na source to a non-linear model accounting for SiPM saturation. These points are fitted to a non-linear response model that accounts for SiPM saturation and electronic nonlinearity. The proposed calibration produces stable photopeak positions across the detector and achieves an energy resolution of 15.2% at 511 keV, while preserving the DOI-resolved flood maps required for high-granularity event's positioning by PET imaging techniques.

Random Coincidence Correction for Inter-Crystal Scatter Events in PET

(#2588)

Hyeongseok Shim[1,2], Guen Bae Ko[2]

Abstract

Inter-crystal scatter (ICS) events in PET, in which a 511 keV photon deposits energy across multiple crystals, offer a route to higher effective sensitivity but are conventionally discarded by photopeak windowing. Prior work has focused on positioning the first-interaction crystal, yet positioning alone does not translate ICS recovery into a system-level sensitivity gain: accepting ICS events requires lowering the lower-level discriminator, which sharply increases the singles rate and raises three issues that have not been jointly addressed, how to group raw singles into candidate ICS events, how to reject uncorrelated groupings of independent-photon singles, and whether the resulting triple coincidences are compatible with the dual-coincidence random-correction framework. This study presents a unified pipeline that addresses all three. Candidate ICS events are formed from list-mode singles and screened for type-1 randoms (false ICS) by a joint timing–distance gate, suppressing the singles-level ICS-to-PE ratio from 15.5–18% to 7–7.5% with negligible activity dependence. Validated PE and ICS events are then paired into PE–PE and PE–ICS prompt coincidences, and the singles-prompt (SP) framework is extended to ICS events by symmetric deflation of the measured ICS rate, yielding a type-resolved SP estimator for type-2 random correction. Validated through GATE simulations of the Pharos PET scanner (Brightonix Imaging; Seoul, Korea), the type-resolved SP estimator achieves $\hat{R}/R_{true}$ = 0.97–1.01 for PE–ICS coincidences across six activity conditions

(200–667 μCi), outperforming the unified strategy and standard delayed-window and singles-rate methods. The complete pipeline delivers approximately 13% additional net true coincidences over a PE-only baseline, with essentially activity-invariant gain across the operating range examined.

A Software-Based Coincidence Sorters for Simultaneous PET Emission and Lu-176 Intrinsic Transmission Data Extraction (#1792)

Xin Zhao, **Xin Zhao**, Zhao Wang, Zhao Wang, Zhaoheng Xie, Zhaoheng Xie

Peking University, Beijing, China

This work was supported by National Natural Science Foundation of China (62394311) and National Biomedical Imaging Facility Grant.

Abstract
Conventional PET coincidence sorters focus on emission events, disregarding intrinsic Lu-176 background radiation in LYSO (Lutetium-Yttrium Oxyorthosilicate) crystals as unwanted noise. To enable simultaneous acquisition of emission and intrinsic transmission data, we developed a software-based multi-window coincidence processor capable of extracting mixed-energy coincidence events from list-mode singles data. The processor utilizes geometric constraints and a dynamic time-of-flight (TOF)-based limit to filter candidate pairs. To suppress severe 511 keV's backscatter contamination in the 202 keV transmission window, a dual-condition rejection strategy was integrated, reducing residual crosstalk to 15.9%. Quantitative validation against Monte Carlo simulation ground truth showed good agreement in count statistics, sinograms, and radial profiles. Tomographic reconstructions successfully recovered phantom structures, validating the fidelity of the simultaneously extracted emission and intrinsic transmission coincidences.

Characterisation of Positron Emission Particle Tracking (PEPT) Performance for In-vivo Blood Flow Estimation in Preclinical PET (#1869)

Laurence Vass, Tia Gibson, Rafa De Torres, Paul K. Marsden

King's College London, School of Biomedical Engineering and Imaging Sciences, London, UK

Abstract

Positron Emission Particle Tracking (PEPT) enables tracking of individual radiolabelled particles and is widely used in industrial applications (e.g. fluid dynamics), but remains underexplored for biomedical use. We recently demonstrated whole-body *in vivo* tracking of single nanoparticles in mice using a preclinical PET scanner, showing transit through the vasculature from the injection site. However, murine blood flow varies from a few to several hundred mm/s. Within this range, the conditions under which PEPT can reliably resolve motion remain poorly characterised. Trajectory estimation depends on a complex interplay between activity, particle velocity, acquisition settings (e.g. energy window, temporal sampling), and algorithm parameters, which have not been explored for murine blood flow estimation.

We address this by establishing a controlled framework to evaluate PEPT performance on a 3-ring PET/CT system (Mediso nanoScan 123S). A modified FLSUN 3D printer generated programmable trajectories of Ga-68 radiolabelled beads (0.4–350 kBq) at speeds of 6–170 mms^{-1}. Ground-truth motion was validated via high-frame-rate video and frame-by-frame analysis. Trajectories were reconstructed using the Birmingham method; estimated speeds and positions were compared to ground truth to quantify accuracy and localisation error.

Our results show that tracking a single particle at speeds up to 50 mms^{-1} with RMSE <2.5 mm requires activity >1.2 kBq. At ≥0.7 kBq, speeds had 18–34% error with large RMSE. At ≤0.5 kBq, trajectories were not reliably resolved. Localisation error increased with decreasing activity and increasing speed, exceeding 10 mm RMSE in low-activity, high-speed regimes. These findings suggest activities >1.2 kBq are required for reliable intravascular speed estimation.

Evaluation of Sparse-Geometry Designs for Long-Axial Field-of-View Preclinical SPECT (#1427)

Elissa L. Avila[1], Lorenzo Confalonieri[1], Xiaochuan Pan[3], Chin-Tu Chen[3], Elena M. Zannoni[1,2]

[1] The University of Texas at Austin, Walker Department of Mechanical Engineering, Austin, USA; [2] The University of Texas at Austin, Department of Diagnostic Medicine, Austin, USA; [3] The University of Chicago, Department of Radiology, Chicago, USA

We thank the Rising Faculty Science and Technology Acquisition and Retention (STARs) Program, The University of Texas System, for the generous support.

Abstract

This study presents the design and preliminary performance evaluation of a long-axial field-of-view (LA-FOV) preclinical SPECT system for small-animal total-body imaging (TBI) [1]. The proposed full scanner consists of 240 CZT detectors distributed across 10 panels and coupled with a multi-pinhole collimator. The system offers a FOV of 74 mm in diameter, ideal for rat imaging, a high-sensitivity central region of 37 mm in diameter tailored for mice, and an axial coverage up to 20 cm.

System performance was characterized through simulations to compute the system response function, 3D sensitivity map, and reconstructed image quality, assessed using a digital long-axial Derenzo phantom under both noiseless and Poisson-noise conditions. A 50% checkerboard sparse configuration was compared against the full configuration [2-3]. While the sparse configuration yielded a proportional 50% reduction in sensitivity, the volumetric uniformity was preserved. Both configurations achieve similar spatial resolution. In noiseless conditions, both can resolve hot rods as small as 1.62 mm with average peak-to-valley ratios (PVR) of 4.35 (full) and 5.32 (sparse). Under noisy conditions, both configurations can fully resolve the 1.93-mm hot rods with average PVR of 7.22 (full) and 7.58 (sparse). Notably, this performance is consistent along the 20 cm axial extent of the phantom.

Future work will evaluate spiral sparse geometries at sparsity levels of 25%, 33%, 66%, and 75% to characterize the degradation of image quality, with quantitative analysis in terms of contrast-to-noise ratio and contrast recovery coefficient. This work supports a pathway toward cost-effective LA-FOV preclinical SPECT instrumentation suitable for TBI.

Feasibility study of ^{68}Ga/^{18}F multiplexed PET imaging on a total-body PET scanner (#2284)

Wen He[1], Craig S. Levin[1,2]

[1] Stanford University, Department of Radiology, Palo Alto, USA; [2] Stanford University, Departments of Electrical Engineering, Bioengineering, and Physics, Palo Alto, USA

This work was supported in part by a grant from the Neuroendocrine Tumor Research Foundation (NETRF).

Abstract

Multiplexed PET (*m*PET) enables simultaneous multi-tracer imaging by detecting prompt gamma in positron plus prompt gamma emitters for triple-photon coincidence tagging, thereby distinguishing them from pure positron emitters. ^{68}Ga is a commonly used PET isotope and emits a prompt gamma at 1077 keV in ~1% of its positron decays. In this study, we assessed the feasibility of ^{68}Ga/^{18}F *m*PET on the GE Omni 128 cm total-body PET/CT using Monte Carlo simulation.

The scanner model was validated against NU2-2018 sensitivity and NECR measurements. A NU2-2018 image-quality phantom was simulated with a 1:1 ^{68}Ga/^{18}F background (2.65 kBq/mL per isotope) and 4:1 hot-to-background ratio, with the two largest spheres assigned to ^{18}F and the four smaller spheres to ^{68}Ga to represent a challenging case for triple-coincidence detection. Isotope unmixing employed an “alternating-update joint EM (AU-EM) algorithm” that we developed with a prompt-gamma detection efficiency map simulated from a ^{68}Ga point-source array.

The simulation yielded 3.46 billion double and 57 million triple coincidences; triple events were dominated by randoms (55.6%), with ^{68}Ga true triples comprising 7.1%. Using true events only, AU-EM reconstructions successfully separated the ^{68}Ga and ^{18}F distributions and achieved percent contrast comparable to OSEM reconstructions from ground-truth events, although percent background variability was degraded. These results demonstrate the feasibility of ^{68}Ga/^{18}F *m*PET on a total-body PET scanner and motivate future work on random triple-coincidence estimation, variance reduction methods, and experimental validation.

Abstract

Positronium lifetime imaging (PLI) enables probing tissue microstructure via the lifetime of ortho-positronium (o-Ps). Robust voxel-wise lifetime estimation remains limited even for high-sensitivity long axial field-of-view (LAFOV) positron emission tomography (PET) systems due to a combination of low detection sensitivity for triple-coincidences and variability in o-Ps lifetime (o-PS-L) extraction methods. In this work, three established approaches for o-Ps-L estimation are presented: least-squares fitting (LS), Bayesian fitting (B), and exponential fitting of the late decay tail (LT). These methods were systematically evaluated using inorganic samples (Quartz, wet and dry Amberlite XAD-4) prepared with I-124. Data were acquired on a Siemens Healthineers Biograph Vision Quadra system in single event acquisition mode and analyzed using time difference distributions (TDDs). The o-PS-L for the Quartz sample was measured to be 1.572 | 1.573 | 1.574 ns (LS | B | LT), wet XAD-4 2.381 | 2.381 | 2.798 ns and dry XAD-4 2.719 | 2.719 | 2.915 ns. LS and B approaches showed consistent results across all samples, while the LT method exhibited systematic deviations under reduced o-Ps contribution. A subsampling analysis identified a minimum of 2500 events per TDD for stable o-PS-L estimation within 5% deviation from the full-statistics result. Based on this constraint, voxel-wise lifetime imaging was demonstrated in a metastatic thyroid cancer patient following injection of 37 MBq I-124 using a 15 min acquisition. To satisfy required statistics, a voxel size of 32 mm was selected, and lifetime estimates were restricted to regions with sufficient counts. These results identify count statistics as primary limiting factor for clinically viable PLI and define a practical threshold for stable voxel-wise lifetime imaging. Future work will focus on extending acquisition times to enable higher spatial resolution and improve robustness for clinical applications.

Abstract

The Patlak plot is a widely used kinetic modeling method for estimating the tracer net influx rate K_i in dynamic PET imaging. However, the requirement for a full time course input function limits its routine clinical use. The Relative Patlak (RP) plot mitigates this constraint effectively by reducing the required acquisition time. Nevertheless, the quantified RP slope K_i' introduces a time-dependent and subject-specific scaling factor relative to K_i, reducing the reliability for inter-subject analysis. In this study, we propose an Intercept Graphical (IG) plot with an associated normalization that requires the same imaging duration as the RP method. The quantified parameter K_{IG} has a time-independent and approximately subject-independent scaling factor for estimating K_i. We evaluated the proposed method using total-body dynamic PET images of 12 healthy and 10 cancer subjects. To evaluate inter-subject quantification performance, multi-organ and lesion K_i' and K_{IG} were generated using the RP and IG methods, respectively, and then rescaled using population-mean scaling factors to recover K_i. Using the Patlak K_i as the reference standard, the organ or lesion K_i estimated by the population-rescaled IG had an error that was 50–70% lower than that of the population-rescaled RP. Furthermore, group analysis indicates the K_i yielded by the population-rescaled IG exhibits statistical behavior more similar to that of the Patlak K_i and outperforms the population-rescaled RP K_i. Overall, the proposed IG approach with normalization retains the low imaging time requirement and improves inter-subject quantitative robustness. It may enable more accurate K_i quantification and improve the clinical feasibility of PET parametric imaging.

Abstract

The selection of compartmental models for dynamic PET analysis is compromised by three key scenarios—the unknown kinetics of novel tracers, mixed kinetics resulting from tissue heterogeneity and spillover, and the diverse multi-organ kinetics in total-body PET—where conventional model selection using nonlinear least squares and Akaike Information Criterion can fail. For this, we augmented our previous framework--kinetic parameter posterior estimation using generative consistency models--to perform Bayesian model selection. The objective is to simultaneously estimate both the model probability and the posterior distributions of the kinetic parameters across six commonly used kinetic models. The method involves training the consistency model on 6,000,000 simulated time-activity curves. Evaluation against a conventional method demonstrates significant improvements; across 6,000 simulated time-activity curves, the proposed method achieved an overall model selection accuracy of 86%, substantially outperforming the 34% accuracy of the conventional method. Furthermore, application to clinical total-body positron emission tomography data from a patient with metastatic cancer yielded physiologically plausible model selection maps that successfully differentiated complex underlying regional kinetics, such as healthy liver tissue versus tumour. Our results indicate that this proposed framework is useful in kinetic model selection in dynamic total-body PET and can have potential for evaluating new radiotracers in clinical practice.

Abstract

Targeted Alpha Therapy (TAT) requires dedicated imaging infrastructure capable of tracking alpha-emitting therapeutics and their daughters in vivo across a wide energy range. We present the experimental imaging performance of AlphaSPECT — a whole-body CZT-based clinical SPECT scanner comprising 32 detector panels integrating 512 micro-pinhole cameras in a dual field-of-view (FOV) configuration. Each panel integrates 16 CZT detectors (20×20×6 mm³, 500-µm pixel pitch) bump-bonded to HEXITEC ASICs. A CT-derived precision rotating gantry enables seamless switching between a large-FOV mode (5-mm pinholes, 40×40×20 cm³) and a high-resolution mode (2-mm pinholes, 20 cm spherical FOV), with sub-10-µm rotational accuracy. Energy calibration across all panels achieved 4–7 keV FWHM at 122 keV following charge-sharing correction. System response matrices were generated via voxel-driven ray-tracing, with geometry parameters estimated via nonlinear optimization against experimental point-source projections. Phantom reconstructions demonstrate uniform response across all detector panels and qualitative compartmental contrast in a 3D Hoffmann brain phantom (8 mCi Tc-99m, 30-minute acquisition), with resolution-limited blurring and partial-volume effects motivating investigation into angular sampling and reconstruction improvements. Ongoing studies include spatial resolution evaluation using a NEMA-compliant hot-rod phantom, collimator micro-rotation to enhance angular sampling, and joint dual-FOV reconstruction — to be presented at the conference.

Abstract

Boron Neutron Capture Therapy (BNCT) requires precise, real-time monitoring of the distribution of boron neutron capture reactions to maximize its therapeutic selectivity.

This work presents a major hardware evolution of the BeNEdiCTE detector, a SPECT-based system designed to track the 478 keV prompt gamma rays emitted during neutron capture.
The detector is based on a co-doped LaBr3(Ce, Sr) monolithic crystal read out by Silicon Photomultipliers.
The custom readout electronics have been entirely redesigned, utilizing boron-free substrates to eliminate background interference at 478 keV.
Furthermore, the new module features embedded AI on a high-performance FPGA for real-time reconstruction of interaction coordinates (X, Y, and Depth-of-Interaction) of the gamma rays on the scintillator.
To meet the high-flux demands of clinical BNCT, the dead time of the system has been reduced from 5.4 µs to 2.1 µs, and an hardware-based energy discrimination circuit has been designed to process only the small percentage of useful gamma rays across the whole spectrum.

We report on the system's design and its upcoming validation at Nagoya University Accelerator-driven Neutron Source (Japan), marking the first SPECT measurement performed in a clinical-like facility.
Preliminary Monte Carlo simulations using a Derenzo-like phantom demonstrate the system's high spatial resolution and its ability to distinguish lesion-sized volumes with boron concentrations as low as a few hundred ppm.
These results set the stage for the upcoming SPECT validation, which aims to prove the system's readiness for the non-invasive, live monitoring of boron distribution during clinical patient treatment.

Abstract

Targeted alpha therapy (TAT) has shown strong promise for cancer treatment because of its high linear energy transfer and localized cytotoxic effect. However, quantitative in-vivo imaging of TAT radiopharmaceuticals and its daughter remains challenging. The clinically administered activity is typically low, while the emitted gamma rays have low branching ratios, making conventional SPECT imaging sensitivity-limited and often requiring impractically long acquisition times. These limitations restrict accurate assessment of biodistribution, pharmacokinetics, and dosimetry, which are essential for optimizing TAT agents. This study investigates Compton imaging as a high-sensitivity alternative for visualizing TAT radiopharmaceuticals using a 5 cm × 5 cm single-layer 3D position-sensitive cadmium zinc telluride (CZT) camera. We performed a pilot imaging study with the alpha therapy radionuclide 225Ac in a clinical phantom filled with a low concentration of 6.2 kBq/mL surrounded by non-radioactive water. The phantom was scanned at 45° rotational steps with 15-minute acquisitions each, and Compton images were reconstructed to evaluate source localization below clinically relevant low-activity conditions. This is the first time such a low-activity concentration has been imaged in a clinical phantom. The results demonstrate clear visualization of the radioactive inserts, supporting the feasibility of CZT-based Compton imaging for TAT monitoring. Based on these measurements, a multi-head configuration with at least eight detector modules could enable in-vivo imaging of ^{225}Ac daughters of target organs within less than 30 minutes, and is being planned as the next step. Additional experiments with ^{212}Pb further suggest that the proposed approach can operate across a broad photon-energy range. Overall, this work provides experimental validation that compact 3D CZT Compton cameras may overcome key sensitivity barriers in alpha-emitter imaging and support future image-guided TAT.

Abstract

Lu-177, a promising theranostic radionuclide emitting β particles for therapy and γ photons for imaging, enables integrated diagnosis and therapy. Lu-177 imaging is increasingly important in treatments where imaging guides therapy. Previous work has demonstrated the use of scintillator as collimators to achieve simultaneous and separate imaging of F-18 and Tc-99m. In this work, we present a novel three-layer shared detector with variable collimator thickness, enabling simultaneous PET, SPECT, and Lu-177 imaging. The first two crystal layers are perforated, with the top layer functioning as a low-energy high-sensitivity (LEHS) collimator, the top and middle layers combined acting as a low-energy high-resolution (LEHR) collimator and medium-energy general-purpose (MEGP) collimator. This design allows flexible adaptation for Tc-99m and Lu-177 imaging without hardware changes.A 96 mm-diameter system was simulated to evaluate two collimation schemes. Simulation results indicate that for Tc-99m, the system can achieve both LEHS and LEHR imaging, with hot-rod phantom spatial resolution reaching 3.5 mm. For Lu-177 (208 keV), inserting high-density LYSO or BGO in the middle layer improved peak-to-valley ratio compared to GAGG, and BGO yielded 4 mm spatial resolution for hot-rod phantom imaging. This flexible collimator design enhances detector versatility and offers a promising solution for multi-radionuclide theranostic applications. Future work will focus on optimizing collimator thickness and evaluating the performance of a prototype system.

Abstract

Conventional radiotherapy is a well-establish treatment for Non-Melanoma Skin Cancers (NMSCs). In this context, patient-specific quality assurance (PSQA) relies on accurate dose distribution measurements. However, current state-of-the-art technologies do not provide sufficient accuracy in assessing dose deposition within the superficial skin layers.

To compensate for the buildup effect in radiotherapy, a bolus material is commonly applied over the tumor to mimic tissue equivalence. Nevertheless, anatomical changes during treatment, such as tumor shrinkage, may introduce air gaps between the bolus and the skin, potentially leading to underdosage.

To address these limitations, a prototype detector, referred to as DQX, has been developed at Laboratoire de Physique Corpusculaire de Caen and experimentally evaluated at Centre François Baclesse . The device is based on a 100 µm thick plastic scintillator coupled to wavelength-shifting fibers and is designed to measure radiation dose in superficial tissue layers, targeting a relative measurement uncertainty below 1% for a 2 Gy photon beam at depths as shallow as 70 µm beneath the skin surface.

This contribution presents a comparison of the DQX prototype and a range of commonly used dosimetric devices employed in PSQA for conventional radiotherapy. These include tools such as ionization chambers and radiochromic films, each of which exhibits inherent limitations when applied to superficial dose measurements. The evaluation focuses on the response under possible clinical conditions such as air gaps variations. By benchmarking the DQX detector against these established technologies, this study also aims to assess its potential to improve dose verification in the buildup region.

Abstract

Three-dimensional position-sensitive single-crystal CdZnTe detectors (3D-CZT), with energy resolution of ~0.3% FWHM for single-pixel events and ~0.5% FWHM for all events at 662 keV, had been demonstrated previously on detectors with dimensions up to 2x2x1.5 cm^3 (total 6 cm^3).Larger volumesingle-crystalCdZnTe semiconductor gamma-ray detectors are needed to achieve higher intrinsic detection efficiency at higher gamma-ray energies. 4x4x3 cm^3 (total 48 cm^3) 3D-CZT detectors manufactured by Redlen Technologies have been explored for the first time. Energy spectra of Cs-137 were obtained on all three 4x4x3 cm^3 CZT detectors. An energy resolution of 1.05% FWHM at 662 keV was obtained for single-pixel events on one 4x4x3 cm^3 CZT detector #12R2. The feasibility of achieving close to 1.0% FWHM energy resolution on CdZnTe gamma-ray detectors with single-crystal detection volume of 48 cm^3 has been demonstrated.

Abstract

Carrier Dynamics by Pockels Imaging (CDPI) is a novel all-optical, quantitative, and non-invasive method for direct spatiotemporal visualization of charge carrier clouds in CdTe radiation detectors. CDPI achieves micrometer-scale spatial resolution and nanosecond temporal resolution, with sensitivity to electric field differences down to ~2 V/cm – enabling tracking of carrier densities just above the intrinsic level. We directly observe electron cloud formation and evolution, including Gaussian shape preservation, diffusion-driven broadening, and field-dependent reshaping. Under high optical excitation, we resolve space-charge perturbed regimes with cloud expansion due to Coulomb repulsion (width up to 400 µm) and pronounced asymmetric tails due to detrapping processes, possibly correlated with a defective layer near the cathode surface. Crucially, CDPI correlates internal cloud dynamics with external circuit currents, linking microscopic physics to macroscopic detector performance. Although demonstrated in one dimension, CDPI is intrinsically two-dimensional and readily extendable to investigate charge sharing in segmented electrodes or pixel arrays. The technique also supports studies of ultra-high photogenerated charge densities relevant to synchrotron and free-electron laser applications and enables direct visualization of carrier injection from the contacts. CDPI offers a powerful new diagnostic tool for understanding and improving CdTe and other compound semiconductor radiation detectors.

Compton Imaging Capability of 1-cm-Thick Pixelated TlBr Detectors

(#1525)

Keitaro Hitomi[1], Yoshiharu Kitayama[2], Mitsuhiro Nogami[1], Jiyon Lee[3], Kenichi Watanabe[4]

[1] Tohoku University, Department of Quantum Science and Energy Engineering, Graduate School of Engineering, Sendai, Japan; [2] Fukushima Institute for Research, Education and Innovation, Fukushima, Japan; [3] Korea Institute of Nuclear Safety, Division of Radiation Protection for NORM & Cosmic Radiation, Daejeon, South Korea; [4] Kyushu University, Department of Applied Quantum Physics and Nuclear Engineering, Graduate School of Engineering, Fukuoka, Japan

Abstract

Thallium bromide (TlBr) is a promising compound semiconductor for the fabrication of gamma-ray detectors because of its high atomic numbers (Tl: 81, Br: 35), high density (7.56 g/cm^3), and wide bandgap energy (2.68 eV). The Compton imaging capability of 1-cm-thick pixelated TlBr detectors was characterized in this study. Pixelated TlBr detectors were fabricated from a crystal grown by the traveling molten zone method using zone-purified material. The crystal size for the detector was 12 mm x 12 mm x 10 mm. The electrodes were formed on the two 12 mm x 12 mm surfaces by vacuum deposition of Tl, followed by Ni and Au. The anode consisted of nine pixel electrodes (2 mm x 2 mm each) surrounded by guard electrodes. The cathode on the opposite side was a planar electrode. For single-pixel events, the TlBr detector exhibited energy resolutions of approximately 2% full width at half maximum or better at 662 keV for all nine pixels with depth correction and event selection based on electron drift time. Compton images of a ^{137}Cs gamma-ray source were obtained using non-adjacent two-pixel events via

the list-mode maximum likelihood expectation maximization (LM-MLEM) algorithm. Clear images of the source were reconstructed at positions consistent with the actual source locations. These results demonstrate that the TlBr detector fabricated in this study possesses high energy resolution and Compton imaging capability.

Abstract

This work presents a study of the influence of X-ray irradiation on the electric field profile in biased CdTe sensors with blocking contacts. The investigation focuses on the modification and potential stabilization of the internal electric field through controlled irradiation of the blocking anode under varying conditions. To emulate realistic detector operation, a silicon wafer was positioned in front of the anode to represent a readout chip, while the cathode was probed by laser-induced transient current technique to determine the electric field. A synchronized pulsed bias scheme enabled time-resolved monitoring of polarization dynamics. Transient current waveforms were recorded in a shielded setup with controlled X-ray exposure, and their temporal evolution was analyzed to assess changes in the electric field profile. The results show that, under dark conditions, the sensor exhibits pronounced space charge formation due to blocking anode. In contrast, appropriately tuned X-ray irradiation of the anode leads to a significant stabilization of the field within the sensor bulk. Under these conditions, the electric field remains nearly uniform over time. The observed behavior reflects the interplay between space-charge formation and X-ray–induced carrier generation, which can partially compensate accumulated charge, although the process remains sensitive to irradiation conditions and contact configuration. Furthermore, low-energy X-ray irradiation transmitted through a silicon layer produces effects comparable to optical excitation at the anode, indicating a similar mechanism of near-contact carrier generation. The presented results provide insight into the control of polarization effects and contribute to improving the operational stability of CdTe-based radiation detectors.

Abstract

Lead halide perovskite single crystals are promising for photon-counting radiation detection due to their high atomic number and favourable charge-transport properties. However, most perovskite detectors operate in hole-transport configurations, while currently existing readout electronics are optimised for electron collection. Bridging this mismatch requires a clear understanding of carrier-polarity-dependent transport and the underlying device physics governing perovskite detectors. We conducted polarity-resolved α-particle (^{241}Am, 5.48 MeV) measurements on $FAPbBr_3$ planar detectors (Au/$FAPbBr_3$/Bi). Polarity-resolved α-particle measurements reveal strongly asymmetric degradation, with irreversible degradation localised beneath the Bi contact, whereas the Au interface develops a defect-rich recombination region that can be mitigated by ultrathin Ti or Cr interlayers, enabling stable bipolar transport operation. Detectors remain stable after ~100 h of continuous biasing at 5,000 V cm^{-1} and ~3 months of shelf-life storage. The combination of high-quality crystals and interfacial protection layers enables the detectors to achieve 1.3% energy resolution for 662 keV (^{137}Cs γ-ray source) and 6.1% for 5.48 MeV α-particles in an electron-transport configuration. This work establishes interfacial degradation as the dominant performance-limiting factor in perovskite radiation detectors and identifies interfacial engineering as the key pathway toward stable and high-resolution electron-transport spectroscopy.

Abstract

The newly upgraded Swiss Light Source (SLS) 2.0, a fourth-generation synchrotron, has begun operation. Photons with energies up to 80 keV will be available at increased flux compared to the third-generation source it replaces. In particular, the brilliance is expected to increase by two orders of magnitude. In this energy range, silicon is no longer an efficient detection material. High-Z semiconductors are therefore required, with GaAs:Cr, CdTe, and CdZnTe being promising candidates. Single sensors (2 × 2) cm^2 made up of 256 × 256 pixels with a 75 µm pitch have been bump-bonded to the JUNGFRAU readout ASIC. Developed at PSI, JUNGFRAU is a charge-integrating readout chip with three gain levels and dynamic gain switching. In this talk, we will discuss the ongoing characterisation of high-Z sensors using JUNGFRAU, with a focus on charge transport properties of CdZnTe produced by Redlen Technologies. Furthermore, recent efforts to improve the linear dynamic range of JUNGFRAU in electron collection mode will be discussed. We will also look towards the future with a discussion of full JUNGFRAU modules using GaAs from Dectris or recently acquired (4 × 4) cm^2 CdZnTe sensors from Redlen. Additionally, the new MATTERHORN photon-counting ASIC has been designed for both silicon and high-Z sensors, with assemblies using GaAs undergoing characterisation.

Abstract

We characterized a Timepix4 application-specific integrated circuit bonded to a 1-mm-thick cadmium telluride sensor for photon-counting X-ray imaging in the diagnostic energy range. A per-pixel energy calibration was performed using X-ray fluorescence and gamma-ray sources, followed by a cluster-wise linear correction to compensate for spectral distortions associated with multi-pixel charge sharing and front irradiation. Flat-field, photon-counting, and spectral imaging tests were performed using a tungsten-anode microfocus X-ray tube operated at 80 kV. The detector achieved an energy resolution of 3.3 keV at 59.5 keV for the Am-241 source. Spectral images were reconstructed using 1 keV energy bins after offline clustering and fluorescence recovery correction. The detector demonstrated high-quality radiographic imaging capability after flat-field correction, despite spatial inhomogeneities typical of fine-pitch CdTe hybrid pixel detectors. A limiting spatial resolution of 8 lp/mm at 10% modulation transfer function was measured for the detector biased at -450 V, at a counting rate approaching 10^7 cps per chip. The results demonstrate the potential of the Timepix4 CdTe assembly for spectral imaging applications.

Abstract

Metal halide perovskites emerge as promising materials for direct X-ray detection due to their high absorption efficiency, favorable charge-transport properties, and compatibility with scalable fabrication methods[1, 2]. While thin polycrystalline perovskite films integrated with pixelated electronics have already demonstrated high-resolution imaging[3], extending these approaches toward thicker highly crystalline absorbers remains essential for practical low-dose applications. Here, we investigate several perovskite multi-pixel detector architectures coupled to charge-integrating readout electronics for low-dose X-ray imaging. The developed devices exhibit stable operation, uniform photoresponse, and spatial resolution approaching pixel pitch limit. Highly crystalline film $CsPbBr_3$ detectors demonstrate spatial resolution up to 20 lp mm^{-1}, keeping high X-ray absorption and efficient charge collection together with scalable fabrication potential, while bulk single-crystalline integrated absorbers provide further improvements in charge collection and uniform low-dose response. Thick 3-4 mm single crystal sensors achieve modulation transfer function values of 35% at the Nyquist frequency under X-ray doses as low as 4 μGy_{air} with a detective quantum efficiency of 48%. In addition, we demonstrate high-contrast radiographic imaging of packaged integrated circuit and computed tomography of small multi-material objects, highlighting the potential of perovskite detectors for next-generation high-resolution imaging systems.

Next Generation Room Temperature Semiconductor Detectors, Sources, and Methods for Computed Tomography in Aviation Security

(#2984)

William C. Barber[1], **William C. Barber**[1]

[1] Rapiscan Systems, Detectors, Torrance, USA; [2] Rapiscan Systems, Detectors, Torrance, USA

Some work supported by the DHS S&T Directorate under Contract No. 70RSAT18CB0000002 and Contract No. 70RSAT21CB0000022. Any opinions, findings, conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the DHS.

Abstract

Advanced X-ray imaging is a principal pillar supporting aviation security and provides materially segmented images of bags, luggage, and cargo. The images are processed to provide a high probability of detection for contraband and/or threats, at an acceptably low false alarm rate to allow sufficient throughput. As the list of contraband and threats increases, the challenge to maintain a high detection probability at a low false alarm rate is advancing the state of art in detectors, sources, scanning methods, reconstruction, recognition, and decision, with the goal of clearing items for air transport. Room temperature semiconductor detectors are currently being used in commercially available diffraction scanners. These are based on pixellated Cadmium Zinc Telluride spectroscopic detectors, which are being developed further for better performance and lower cost. Cadmium Telluride and Cadmium Zinc Telluride photon counting detectors are currently being developed for potential use in multi-energy transmission scanners to improve detection and lower false alarms compared to the dual-energy dual-layer scintillator based scanners that are in wide use. Sensor performance requirements and cost constrains for widespread use of room temperature semiconductor detectors in both transmission and diffraction scanners are presented, with a focus on next generation computed tomography methods in multi-modal system of systems approaches to achieve the imaging workflows required for aviation security. Detector array and source geometries to achieve combined transmission and diffraction imaging in the different concepts of operation for the various scanning applications in aviation security are discussed.

A new compact prototype for 3D gamma coded-aperture spectro-imaging (#1218)

Giulia Rosso, Guillaume Amoyal, David Fras, Quentin Gendre, Maugan Michel, Dominique Tromson

Université Paris-Saclay, CEA List F-91120, Palaiseau, France

Abstract

During nuclear dismantling, remote measurements, as radiation gamma imaging, are particularly advantageous since they reduce the risk for users, providing a visual map of radioactivity even in inaccessible environments. However, 2D gamma imaging does not directly provide the distance between source and detector, neither the 3D localization of the source. The goal of this work is to overcome these limits by developing a new compact and light 3D coded-aperture spectro-imager for applications in nuclear dismantling. This study presents the developments of the prototype, consisting of a coded-aperture gamma spectro-imager and an RGB-D (color and depth) camera, in carrying out 3D gamma imaging in experimental laboratory conditions. The device weight 325 g, with dimensions of 18 × 10 × 2.8 cm, and can distinguish among the most common radionuclides in the nuclear industry with energies ranging from the 59.5 keV gamma ray line of 241Am, up to the 60Co 1332 keV emission. The 3D hotspot localization and reconstruction are achieved with a triangulation from different viewpoints, which is made possible using a SLAM (Simultaneous Localization And Mapping) algorithm. We tested the prototype using point-like radioactive sources both in single and multiple sources configurations. In both cases, using a minimum of three static poses of few minutes' duration, the sources localizations are correctly achieved with errors in the order of 2 cm for measurements taken at almost one meter. New tests on volumetric and extended sources are currently on-going.

Abstract

Spectral photon counting technology (SPCCT) represents a critical leap for security screening, offering high-resolution imaging and accurate material identification to reduce false alarms and detect threats invisible to legacy systems. SureScan Corporation utilizes SPCCT and dual-energy CT (DECT) in airport explosive detection systems (EDS), focusing R&D on characterizing prototype components like the AMS-OSRAM AS5920M. This state-of-the-art, 4-side buttable system-in-package (BSIP) module features direct-conversion CdZnTe crystals with 341µm x 365µm pixels integrated with ultra-low noise ASICs. Each ASIC supports five configurable energy thresholds and operates with short dead times to sustain high photon flux without significant pile-up. Our performance evaluation includes per-bin count rates, spatial uniformity, and spectral fidelity under various beam conditions, alongside imaging metrics such as modulation transfer function (MTF) and detective quantum efficiency (DQE). Furthermore, we demonstrate the importance of spectrum unfolding to correct non-ideal detector responses. By utilizing energy response function models derived from synchrotron measurements at Brookhaven National Laboratory, we reconstructed true incident energy spectra, significantly improving the accuracy of material identification through proprietary empirical decomposition methodologies.

Abstract

For low-flux radiation imaging applications such as gamma-ray imaging, nuclear medicine, and X-ray diffraction, spectral and spatial resolution are performance drivers.However, detector efficiency is essential as it determines the quantity of information collected. The primary challenge is to achieve high-resolution performance at a reasonable cost. Then, it becomes possible to increase detection volume and the amount of information that the system can gather within a limited time.

Our HiSPECT CZT detector module addresses this challenge through several key principles: the anode is segmented into large pixels, which limits charge sharing, while high spatial resolution is achieved through sub-pixel positioning. The low electronics density reduces cost, power dissipation, and improves yield. Additionally, the absence of cathode readout simplifies integration, while the depth of interaction is retrieved through multiple anode readouts.

In this work, we present how modules are combined to build larger systems, detailing the readout electronics and showcasing various imaging application cases, including coded aperture, collimator, positron, and Compton imaging modes.

Activity Quantification Using Experimentally Imaged Source Distributions (#2702)

Christopher G. Wahl, **Christopher G. Wahl**, Reid Sobota, Reid Sobota, David Goodman, David Goodman, Joseph Ghezzi, Joseph Ghezzi

H3D, Inc., Ann Arbor, USA

Abstract

Radioactive source activity quantification is critical in many applications. A limiting factor in estimating activity is often knowledge of the source distribution within a medium since the position of the activity can greatly impact the observed counts at the detector. Algorithms have been developed to use a Compton and coded aperture gamma-ray imaging detector to image the source distribution within the volume of interest using a set of stationary measurements or a free-moving measurement with a simultaneously localization and mapping (SLAM) system. The iterative 3D volumetric imaging algorithm will be described. The imaged source distribution can then be used to improve activity quantification over a uniform source assumption. This is demonstrated with measurements of various geometries.

Abstract

Fully spectroscopic photon-counting CT enables material identification by recording the energy-dependent transmission spectrum of an object. Timepix3 (TPX3) detectors extend conventional threshold-based photon counting CT by recording position, time-of-arrival and energy information for individual events, allowing for post-acquisition energy binning and extraction of spectral features such as K-edges. However, fully spectroscopic photon counting CT with TPX3 detectors remains limited by detector area, photon statistics, scan time and raw data volume.

Previous work introduced a two-stage TPX3 acquisition scheme that combines frame-based and event-based readout. Here, we investigate whether the frame-based TPX3 intensity image can be replaced by a geometrically matched flat-panel intensity measurement. The CMOS/GdOS flat-panel detector provides full-field intensity projections, while a 12 x 1 TPX3 array with 1 mm CdTe sensors provides fully spectroscopic region-of-interest (ROI) information. The method combines the low-noise intensity information of the flat-panel detector with the material-specific spectroscopic information of TPX3. Projection geometry is matched by adapting cone-beam magnification, followed by empirical intensity mapping in the overlap region. The approach is benchmarked against the original TPX3-MPX-normalized acquisition reference. Initial results indicate that replacing the TPX3 intensity image with flat-panel projections preserves TPX3-derived material characteristics in the investigated ROI and enables material labels to be extrapolated to repeated structures in the full-field reconstruction.

Abstract

Cherenkov Charge Induction (CCI) detectors consist of transparent semiconductor detectors that combine the conventional charge induction readout with the detection of Cherenkov light generated by gammas depositing energy above the Cherenkov threshold. CCI detectors show strong potential for applications requiring time-resolved multi-MeV gamma detection, such as proton range verification in proton therapy.

In this work we report on a pixelated CCI TlBr detector consisting of a 14×14×11 mm3 TlBr crystal with a 4×4 pixelated anode matrix of 2.3×2.3 mm2 pixels with 2.5 mm pitch. The lateral faces of the crystal were polished to maximize light extraction, and a 2×2 silicon photomultiplier (SiPM) array with 4×4 mm2 active area per channel was used for Cherenkov light detection. The detector was instrumented with a multi- channel acquisition system based on a CAEN R5560 open FPGA digitizer, enabling simultaneous acquisition of charge induction and Cherenkov light signals from all detector channels. The acquisition was triggered by the Cherenkov readout and a 22Na point source was used for detector characterization.

First results demonstrate the feasibility of simultaneous Cherenkov light and charge induction acquisition using a multi-channel readout, with the optical signal successfully providing the acquisition trigger and a timing reference to estimate the electron drift time. Future work will focus on optimization of the triggering and synchronization scheme, waveform processing methods, and detector operating conditions to improve event selection and detector characterization.

Abstract

Cadmium Zinc Telluride (CZT) detectors are widely used for X-ray and γ-ray detection due to their high atomic number, wide band gap, and excellent room-temperature performance. Their response is governed by charge transport processes, including carrier mobility, trapping, diffusion, and electric-field nonuniformities, which are critical in pixelated geometries where charge sharing and weighting-field effects dominate signal formation. In this work, a 3D CZT detector model is developed in COMSOL Multiphysics, solving semiconductor transport equations self-consistently without Gaussian charge-cloud approximations. Signal induction is computed using the Ramo–Shockley theorem applied to the full carrier distribution. Validation against synchrotron measurements shows excellent agreement in normalized charge collection profiles (r = 0.98), confirming accurate reproduction of charge transport and sharing effects.

Abstract

Depth-of-interaction (DOI) estimation in CdZnTe detectors is conventionally based on the cathode-to-anode amplitude ratio (C/A), while timing-based methods have been explored as alternative indicators in pixelated geometries. However, DOI characterization in cross-strip CdZnTe detectors using digitized waveform signal parameters, including drift time, cathode amplitude, and anode rise time, and the degree to which these parameters provide independent depth information has not been systematically studied. In this work, we present a waveform-based DOI characterization of a 5 mm thick cross-strip CdZnTe detector (7 anode strips, 8 cathode strips, and 1 steering electrode). A collimated ^{137}Cs slit beam was scanned across 26 discrete depth positions 0.2 mm apart. Drift time and cathode amplitude exhibit a strong correlation (R^2 = 0.99), establishing that both contribute to the practical lower bound on the achievable single-event depth resolution. At each collimator slit position, the measured signal distributions reflect the distribution of interaction depths, due to finite beam width and intracrystal scatter. The C/A ratio computed from the two highest-amplitude cathode strips provides the best trade-off between DOI resolution and measurement consistency. Using a leave-one-step-out cross- validation framework, we obtain a DOI resolution of 1.35 mm RMSE with single-feature calibration and 1.12 mm RMSE using a 9-feature random forest regression model.

Ultra-High Resolution CZT Gamma Camera Using Machine-Learning Based 3D Interaction Localisation (#2496)

Nathan Atkins, Matthew Exley, Ian Baistow, **Alexander Cherlin**

Kromek Ltd., Sedgefield, UK

Abstract

An ultra-high resolution CZT gamma camera platform is presented, integrating advanced detector readout, machine learning (ML) based signal processing and practical calibration procedures for sub-pixel 3D interaction localisation. The system employs Kromek's D-Matrix readout with 2 mm pixel pitch detectors and utilises an ML model trained on physics-based simulations and calibrated with experimental flood-field data. Recent developments focus on improving calibration flexibility, robustness to detector performance fluctuations and stability during prolonged operation through refined detector simulations, multi-model optimisation strategies and incorporation of measured data in the training process.

Performance evaluation demonstrates improved spatial uniformity and significant suppression of inter-pixel artefacts in uncorrected flood field images, with stable behaviour maintained over extended acquisition periods without recalibration. Previously reported intrinsic spatial resolution (~250 µm) and depth-of-interaction accuracy (~0.5–1 mm) are preserved, with improved consistency across the detector volume. Reduced reliance on flat-field correction limits amplification of Poisson noise in reconstructed images, enhancing effective image quality. The ML predicted energy incorporates corrections that effectively eliminate energy DOI dependence and charge sharing losses, resulting in a strongly reduced low-energy tail of the spectrum.These results demonstrate a robust and scalable CZT gamma camera platform, addressing key practical limitations of earlier implementations. The integrated detector, calibration and ML based data processing framework enable reliable high-resolution imaging under realistic operating conditions and supports straightforward scaling to larger field-of-view systems. A full-scale camera is currently under construction, highlighting the potential for integration into advanced nuclear imaging applications.

Abstract

Hybrid semiconductor detectors based on the TimePIX-family read-out chips enable direct detection of ionizing radiation with high spatial and spectroscopic resolution. This work investigates the application of femtosecond laser ablation for precise structural modification of detector components while minimizing thermal damage and preserving detector functionality. The study focused on three-dimensional shaping of the read-out chip in a MiniPIX TimePIX3 detector with a 1 mm thick cadmium telluride sensor and on edge cutting of silicon sensors. An optimized laser ablation process enables significant thinning of the read-out chip while maintaining full detector operation. The modified configuration allows backside illumination of the detector, resulting in reduced X-ray attenuation and improved detection efficiency for low-energy photons in the energy range from 5 to 25 keV. Experimental measurements also demonstrate improved spectroscopic performance and enhanced spatial resolution. In addition, femtosecond laser ablation was applied to precise cutting of silicon sensor edges, enabling efficient integration of individual modules into large-area monolithic detection systems. The presented results demonstrate that femtosecond laser ablation is a promising tool for advanced modification of hybrid semiconductor detectors and can significantly expand their applicability in future radiation detection systems.

Abstract
High resolution detection modules for multi-isotope SPECT imaging are strongly required in nuclear medicine. In this framework, we proposed and developed new cadmium–zinc–telluride (CZT) drift strip detectors for room temperature gamma-ray spectroscopic imaging. As widely demonstrated, CdZnTe (CZT) is one of the key materials for the development of room temperature X-ray and gamma ray detectors and several research groups are still involved in advances in both device and the crystal growth technologies. The CZT detectors, equipped with orthogonal anode/cathode collecting strips, drift strips and dedicated digital pulse processing allow a detection area of 6 x 20 mm^2, excellent room temperature energy resolution of 0.8% FWHM at 662 keV and sub-millimetre spatial resolution. The timing performance of the detectors will be also presented. These activities are within an Italian PRIN 2022 PNRR project (No. P2022SE49Y; CUP: B53D23024100001), funded by the Italian Ministry for University and Research (MUR).

Abstract
High-resolution Cd(Zn)Te radiation detectors are essential for quantitative imaging in medical diagnostics, high-energy physics, and industrial non-destructive testing [1]. This study examines the impact of charge sharing (CS) [2] in a 2-mm CdTe/Timepix detector with 55 µm pixels [3], and proposes a spectroscopic correction method.

From Am-241 and Co-57 experimental data, we categorized interaction events by their multiplicity and a newly introduced shape descriptor called circularity. Analysis showed that non-circular events (C < 0.9) resulted in energy peaks shifting toward lower energies due to unrecorded below-threshold pixels. To address these high-multiplicity CS events, we developed a multi-stage spectroscopic correction method that corrects spectra based on circularity and multiplicity values. This approach improved the average FWHM for the Am-241 peak from 16.70% to 10.05% and for Co-57 from 9.64% to 6.73%.

Additionally, AllPix-Squared simulations [4] were used to model charge cloud dynamics and quantify losses occurring during both propagation and digitization. This work enabled a more robust energy calibration and unbiased spectroscopic performance for small-pixel semiconductor detectors.

Abstract

Accurate dosimetry of high-energy (≥ 15 MeV) clinical electron beams is challenged by bremsstrahlung-induced photon contamination (X-ray tail), which leads to unintended dose deposition in deep tissues. In this study, high-resistivity CdZnTe (CZT) detectors were investigated for sensitive characterization of this contamination. Two planar CZT detectors (5-mm and 8-mm thick) exhibited high bulk resistivity (~2.0 × 10^{10} Ω·cm) and competitive energy resolution (3.9–4.1% at 662 keV). Measurements were performed using clinical LINAC electron beams (6–18 MeV) at an SSD of 100 cm. To circumvent pulse pile-up under intense photon flux, the detector response was evaluated via time-integrated current in a mixed radiation field. The integrated charge increased markedly at 15 and 18 MeV, indicating enhanced bremsstrahlung production. The 8-mm detector showed higher sensitivity to penetrating photon components than the 5-mm detector, highlighting the importance of detector thickness. These results demonstrate that CZT detectors enable high-sensitivity characterization of photon contamination and are promising for real-time dosimetry and radiotherapy quality assurance.

Engineering Low-Reverse-Current $CsPbBr_3$ Sensor Structures through Surface Passivation and Deposition of Different Contacts (#1094)

Volodymyr Gnatyuk[1], Xinxin Wang [2,3], Juha Kalliopuska[1], Dmytro Nalyvaiko[1], Noriyuki Masuda[1], Sami Vähänen[1], Shimao Wang[3], Gang Meng[3]

[1] Advafab Oy, Helsinki, Finland; [2] University of Science and Technology of China, Hefei, China; [3] Anhui Institute of Optics and Fine Mechanics, Hefei Insititutes of Physical Sciences, Chinese Academy of Sciences, Hefei, China

Abstract

$CsPbBr_3$ single crystals (CPB SCs) were grown by a modified inverse temperature crystallization method and processed to fabricate metal-insulator-semiconductor (MIS) sensor structures. A 5 nm Al_2O_3 layer was deposited by atomic layer deposition to passivate the crystal surface, suppress surface leakage, and provide environmental protection. Pt, Ti, Au, and Al contacts were subsequently deposited to form asymmetric barrier structures with different electrode combinations. X-ray diffraction measurements confirmed high crystalline quality of the as-grown CPB crystals. The rocking curve of the (004) plane exhibited a full width at half maximum of 0.19°. *I-V* measurements demonstrated pronounced rectification in all investigated MIS structures. The $Pt/Al_2O_3/CPB/Al_2O_3/Al$ sample exhibited the lowest reverse current (~ 25 nA at 1000 V) and the strongest blocking behavior. These results confirm that Al_2O_3 passivation combined with optimized asymmetric contacts is an effective approach for engineering low-leakage, polarization-resistant perovskite X/γ-ray sensors.

Additive Engineering of $Cs_2AgBiBr_6$ Double Perovskite Single Crystals: Growth Optimization, Structural Characterization, and Radiation Detector Evaluation (#1418)

Nazire S. Sahsuvar[1], Michael Fiederle[1], Zeynep Cihan[1], Michael Daub[2]

[1] Albert-Ludwigs-Universität Freiburg, Freiburg Materials Research Center (FMF), Freiburg im Breisgau, Germany; [2] Albert-Ludwigs-Universität Freiburg, Institute of Inorganic and Analytical Chemistry, Freiburg im Breisgau, Germany

This work was supported by the BMBF under Grant No. 05K22VFA Perodet.

Abstract

This study presents a systematic investigation of additive engineering strategies for the solution-based growth of all-inorganic $Cs_2AgBiBr_6$ double perovskite single crystals and their evaluation as radiation detectors. Various

chemical additives including toluene, ethyl acetate, thiourea, sodium acetate (NaOAc), and potassium acetate (KOAc) were systematically introduced into the precursor solution to influence nucleation dynamics, crystal size, and structural quality. The combination of NaOAc and KOAc was identified as the most effective additive strategy, consistently producing large (up to 2.2 cm), well-faceted, phase-pure single crystals with high reproducibility. The optimized crystals were characterized using X-ray diffraction(XRD), high-resolution XRD(HR-XRD) with rocking curve analysis, scanning electron microscopy(SEM), energy-dispersive X-ray spectroscopy(EDX), laser-induced breakdown spectroscopy (LIBS), and Raman spectroscopy. HR-XRD rocking curves revealed exceptionally narrow full-width at half-maximum (FWHM) values as low as 0.0144°, confirming outstanding crystalline perfection. Electrical characterization, including current–voltage (I–V) profiling, space-charge-limited current (SCLC) analysis, signal-to-noise ratio (SNR) evaluation, was performed to assess the detector potential of the optimized crystals. While the crystals exhibited high bulk resistivity (~10^9–10^{10} Ω·cm), excellent phase purity, and radiation sensitivity, detector-level investigations revealed trap-limited charge transport and self-trapped exciton formation as intrinsic limitations. This work establishes dual-acetate additive engineering as a robust strategy for growing high-quality $Cs_2AgBiBr_6$ single crystals and provides critical insights into the gap between crystal quality and detector-scale performance.

Abstract
This work builds upon our characterization of lead-free double perovskite $Cs_2AgBiBr_6$ single crystals for radiation detection applications, where high-quality, centimeter-scale crystals (up to ~2.2 cm) were synthesized via a low-cost standard solution-cooling growth method. Structural analysis confirmed a phase-pure cubic $Fm\bar{3}m$ structure with a dominant {111} orientation and narrow FWHM values, indicating high crystalline quality. Morphological and

compositional studies revealed smooth surfaces, uniform morphology, and near-stoichiometric composition, while electrical measurements showed low leakage current, ohmic behavior, and high resistivity (10^9–10^{10} Ω·cm)[4]. Despite these favorable properties, device performance remained limited due to defect-related charge transport.To address this, a constant-temperature, feed-controlled growth approach is introduced, where supersaturation is regulated via continuous precursor feeding under stable thermal conditions. This steady-state method suppresses uncontrolled nucleation and promotes the growth of larger, higher-quality crystals. The approach is expected to reduce defect densities and improve material performance, providing a pathway toward high-performance, environmentally friendly radiation detectors.

Abstract
In this work we determined the peculiarities of high-temperature phase equilibria in the CdTe–MnTe system using a differential thermal analysis method in a thermocycling mode. Temperature dependences of the volume fractions of the liquid and solid phases in $Cd_{1-x}Mn_xTe$ (x=0÷0.5) alloys, as well as the minimum and maximum melting temperatures of the solid phase were obtained. These dependences allowed us to establish critical temperatures of equilibria between the solid phase and the melt and to construct the solidus and liquidus lines of the CdTe–MnTe phase diagram. It was shown that with an increase in the molar fraction of MnTe in alloys ranging from 0.1 to 0.5, the decreases in the temperatures for both the solidus and the liquidus did not exceed 20 °C. Plus, the temperature interval between them remains practically constant at 15-18°C. Also, we determined the temperature intervals of the pre-melting region and found that with an increase in the MnTe fraction, the region of pre-melting states of the

alloys expands. The results described in this work provide more reliable data on the equilibrium between phases, since the method reduces the influence of kinetic limitations of classical thermography.

This study was supported by the German Research Foundation (DFG) and the French National Research Agency (ANR) within the collaborative project “GaN diode array for proton monitoring and imaging”. Project number: DFG-505408069/ANR-22-CE92-0047

Abstract
To fully exploit the high-precision of proton therapy, advanced beam monitoring and quality assurance devices capable of reliable real-time dose verification are essential. This study presents the first performance evaluation of a Gallium Nitride (GaN) pin-diode array at a clinical proton therapy facility using Pencil Beam Scanning. The detector array is comprised of 11x11 diodes with a 500 µm pitch coupled to a low-noise multi-channel readout system, and the response of all 121 pixels was evaluated individually. The experimental characterization was carried out at a cyclotron-based proton therapy center using clinical proton energies of 100 MeV and 226.7 MeV. We investigated the detector response for different single proton spots ranging from 0.02 to 100 monitor units (MU), corresponding to 10^6 - 10^{10} protons. The results demonstrate excellent linearity between diode response and machine output. Regarding the time response characteristics, a bi-exponential decay model expresses the

observed signal fall-off after irradiation. The afterglow contribution was less than 5% of the integrated signal per measured spot. These initial results of a pixelated GaN pin-diode array under clinical pencil beam scanning conditions identify the proposed detector as a promising candidate for both real-time beam monitoring and high-precision quality assurance in clinical proton therapy environments.

Abstract

All-inorganic perovskite $CsPbBr_3$ single crystals are promising candidates for room-temperature radiation detection; however, the conventional vertical Bridgman (VB) growth rates (<1 mm/h) severely constrain efficient growth and wide applications. In this study, we report a novel strategy for preparing high-performance single crystals via zone refining, which integrates the traditionally separate purification and crystal growth processes into a unified in-situ purification and growth process. This strategy accelerates the growth rate to 25 mm/h — approximately 25-fold faster than conventional vertical Bridgman (VB) growth methods — while preserving an X-ray rocking-curve FWHM of just 0.02°. The resulting crystals exhibit exceptional carrier transport properties, with a hole mobility-lifetime product ($\mu_h\tau_h$) of 1.2×10^{-3} cm^2 V^{-1} and a dark current of only 26 nA at 300 V for a 6-mm-diameter circular device. Asymmetric planar detectors fabricated from these crystals demonstrate outstanding room-temperature energy resolutions (ERs) of 7.3%, 5.8%, 5.0%, and 3.3% for ^{241}Am (59.5 keV), ^{57}Co (122 keV), ^{22}Na (511 keV), and ^{137}Cs (662 keV) γ-rays, respectively. This work breaks the crystal growth rate bottleneck and provides a practical pathway toward the scalable in-situ growth of high-performance perovskite $CsPbBr_3$ radiation detectors.

Abstract

Photon-counting detectors (PCDs) enable high spatial resolution, zero electronic noise, and multi-material decomposition. Chromium-compensated gallium arsenide (GaAs:Cr) is an outstanding candidate material for these applications. To address single-crystal inhomogeneities and ASIC-induced variations, we implemented a single-pixel energy calibration scheme based on K-edge absorption for high-resistivity GaAs:Cr detectors [1]. S-curve scans were performed for 0.6 mm, 1.0 mm, and 1.4 mm sensor thicknesses using 0.5 mm metallic filters (Ta, W, Pb). Calculating the differential intensity ratio between filtered and air spectra allowed accurate K-edge energy extraction, yielding highly linear fits ($R^2 > 0.99$) between energy (keV) and Digital-to-Analog Converter (DAC) thresholds. Crucially, incorporating electron mobility-lifetime ($\mu\tau_e$) products elucidates the physical mechanisms driving thickness-dependent gain variations and spectral shifts. Subsequent evaluations confirmed the calibration accuracy. This calibration and physical analysis validate the spectral imaging capabilities of thick GaAs:Cr detectors, advancing their clinical applications.

Optical manipulation of space charge in rectifying CdZnTe/CdTe radiation detectors (#2589)

Samuel Kačenga, Marián Betušiak, Eduard Belas, Roman Grill, Petr Praus

Charles University, Faculty of Mathematics and Physics, Institute of Physics, Prague, Czech Republic

This project is co-financed from the state budget by the Technology Agency of the Czech Republic under the code TQ28000004 Semiconductors4All.

Abstract

This work investigates the polarization and depolarization processes in CdZnTe and CdTe radiation detectors with rectifying contacts. The electrical properties of the contacts were characterized by I–V measurements, while the evolution of space charge was studied using the Laser-induced Transient Current Technique (L-TCT) combined with Monte Carlo simulations of charge transport to determine electric field profiles. In both CdZnTe and CdTe detectors, the gradual formation of negative space charge within the detector volume after applying bias was observed due to the hole blocking anode. Depolarization methods based on optical irradiation were subsequently investigated. In the CdTe detector, continuous above-bandgap irradiation of the anode by a 565 nm diode resulted in a stable, nearly flat electric field profile, demonstrating effective suppression of polarization for at least 1000 s. Similar results were observed for above-bandgap anode irradiation of CdZnTe as well. In both CdZnTe and CdTe detectors, continuous side irradiation by a below-bandgap 904 nm diode decreased the space charge and improved stability as well. However, compared with the above-bandgap anode irradiation, polarization was only partially suppressed for the CdTe detector, and the internal electric field still evolved over time, albeit more slowly than in the dark. For the CdZnTe detector, the side irradiation completely stopped the polarization. The results confirm that controlled optical irradiation can significantly improve the stability of CdTe/CdZnTe detectors operated under bias.

Abstract

Conventional 4H-SiC Schottky barrier detectors (SBDs) with thick active layers (>50 μm) are often limited by high leakage currents and premature breakdown under high bias voltages. This work introduces an innovative approach using an ultrathin yttria-stabilized zirconia (YSZ) high- κ dielectric interlayer to form a metal-oxide-semiconductor (MOS) structure. While YSZ is a known ionic conductor at elevated temperatures, its ionic mobility is effectively frozen at room temperature, allowing it to function as a robust electrical insulator that suppresses carrier injection. Ni/YSZ/n-4H-SiC MOS structures, fabricated via pulsed laser deposition demonstrated stable operation up to 1 kV. The high-voltage stability enabled a depletion width of approximately 70 μm at 1000 V, establishing favorable conditions for efficient charge collection in thick epitaxial layers. Spectrometric evaluation with a triple-alpha source (^{238}Pu–^{239}Pu–^{244}Cm) confirmed enhanced performance, with stable energy resolution maintained across a broad bias range (100–1000 V) and optimal results observed between 200 V and 600 V. This architecture significantly improves high-voltage resilience while maintaining competitive spectroscopic qualities, paving the way for next-generation deep-depletion radiation detectors in nuclear and space applications.

Polycrystalline Based Semiconductors (PBS) TlBr for High Energy X-ray Detection and Radiography (#2790)

Alireza Kargar, Matthias Muller, Arthur Kim, Mike S. Squillante, Jarek Glodo

RMD, Inc., Watertown, USA

This work has been supported in-part by the CWMD/DHS through University of Tennessee, Knoxville (UTK), under competitively awarded contracts: 22CWDARI00047-01-01. This support does not constitute an express or implied endorsement on the part of the Government.

Abstract

TlBr Polycrystalline Based Semiconductors (PBS) are investigated as promising ceramic materials for low-cost, high-energy x-ray detection. Ceramic samples were prepared through hot pressing followed by the fabrication of planar detectors for characterization and x-ray response measurements. Current-voltage (I-V) characteristics were evaluated for all devices, which exhibited high resistivity (≥10^9 Ω cm) and stable performance under applied bias. The samples demonstrated excellent sensitivity to 70 kVp x-rays, as well as outstanding response to 6 MeV and 9 MeV x-ray pulses from the Linatron M9A linear accelerator (linac) at the University of Tennessee, Knoxville (UTK). This work provides a general overview of the ceramic preparation process and detector characterization and summarizes low and high-energy x-ray responses measured at RMD and UTK.

Abstract

This work investigates the influence of Schottky contact size on the charge collection efficiency (CCE) and lateral expansion of the active region in 350 μm thick semi-insulating GaAs detectors using alpha particle spectrometry. Measurements were performed for detectors with Schottky contact diameters ranging from 0.10 mm to 2.00 mm under reverse bias voltages up to 500 V. The results show that detectors with smaller contacts achieve higher CCE values and simultaneously higher counting rates, indicating spreading of the electric collection field beyond the geometrical contact area. The lateral extension of the active region was evaluated from the effective active diameter derived from alpha peak count analysis. The obtained results demonstrate an approximately linear increase of the lateral extension with increasing reverse bias voltage, reaching average values of about 80 μm at 200 V and 120 μm at 300 V. These findings are particularly relevant for pixelated detector systems with small pixel pitch, such as Timepix3-based detectors employing thick GaAs sensors.

Abstract

Understanding charge cloud formation and transport in CdTe detectors is essential for precision spectroscopy, imaging, and Compton polarimetry in the sub-MeV gamma-ray band. We report a detailed experimental study of electron diffusion and electron-dispersion mechanisms in a 2.0 mm-thick CdTe-Timepix3 detector (256×256 pixels, 55 µm pitch), operated at a bias voltage of −300 V and temperature of ≈28 °C. Monochromatic 200 keV and 300 keV gamma-ray beams, collimated to 10 µm×10 µm, were provided by the ESRF ID15A beamline and directed along the detector's Y-axis. A depth-resolved scan was performed in 200 µm steps along the Z-axis, probing the evolution of the transverse charge cloud inside the CdTe volume. For each Z-position, thousands of photoelectric events were selected, and the 1D transverse distribution of the total collected charge was reconstructed along the X-axis. Gaussian fits to these distributions yielded depth-dependent width values. Fitting the squared width values with a function that models all contributions to the transverse charge distribution at the pixelated plane enabled the extraction of key charge-transport parameters: the initial radius of the primary photoelectron cloud and the electron transverse diffusion coefficient. Independent measurements of the electron drift velocity using throughgoing muon tracks were used to constrain this parameter. The measured evolution of sigma values is well described by a model that combines thermal diffusion, the finite initial radius of the primary photoelectron cloud, and Coulomb-driven charge-cloud expansion. This work provides the first depth-resolved experimental quantification of these combined effects in CdTe-Timepix3 detectors, improving charge-transport inputs for simulations of Compton imaging and polarimetry in the 0.1–1 MeV energy band.

Abstract

Methylammonium lead tribromide ($MAPbBr_3$) single crystals are intensively studied emerging materials for use in X-ray radiography and gamma-ray spectrometry [1] and their quality such as shape control, dislocation and point defect densities are improving but some of their properties remain elusive. In particular, transient X-ray-induced photocurrent can be measured in MAPbBr3 single crystals detectors after the bias is switched off. This response then slowly decays over time. In this study, we investigate the internal electrical field that builds up when a bias is applied2[4] by measuring the residual sensitivity of millimeter-thick Cr/$MAPbBr_3$/Cr-based detectors after switching off the bias from 10V to 0V. By fitting a numerical model, we compute the value of this internal field and infer the ionic charge density close to the electrodes. This model is also used to approximate the charge carrier mobility lifetime product.

Abstract

High-performance γ-ray spectroscopy with solution-grown metal halide perovskites has been persistently limited by uncontrolled defect formation during crystal growth. Here, we identify ambient mechanical vibration as a critical yet overlooked factor that destabilizes the concentration boundary layer and perturbs lattice ordering in hybrid perovskite single crystals. The resulting crystals exhibit an increased carrier mobility-lifetime product of 8.36×10^{-2} $cm^{-2}\,V^{-1}$, which contributes to a more efficient charge collection process. Detectors achieved an energy resolution of 9.5% at 59.5 keV and 5.2% at 122 keV. These results establish vibration control as a key principle for high-quality single-crystal growth and scalable perovskite radiation detectors.

Abstract

The study of the electrical properties of perovskite $CsPbBr_3$ crystals, grown by the Bridgman method in our laboratory, showed that the stability of the dark current of the In/$CsPbBr_3$/In structure critically depends on the polarity of the applied voltage. The $CsPbBr_3$ crystal was cut perpendicular to the growth plane. Indium was deposited on both surfaces after treatment in an argon plasma. The contact area was 4x4 mm^2, and the thickness of the plates was 1-2 mm. The study was carried out at a temperature of T≈300 K and a voltage of 100 V. The surface of the sample, which was closer to the beginning of the ingot growth and crystallized first, will be designated as “cold”. When on the “cold” side was the “minus”, the current remained stable over time for 8 hours of

continuous operation, while with reverse polarity, a degradation of the blocking properties wais observed with an increase in the dark current by 2–3 orders of magnitude. A similar phenomenon (non-equivalence of opposite crystal surfaces) was observed in CdTe crystals, oriented in the (111) plane. Therefore, it can be assumed that when cutting a plate perpendicular to the growth axis, with there is a very high probability that one side will be enriched with a layer of Cs and Br atoms, and the opposite side, which is more chemically active, will be enriched with Pb and Br atoms. This may be the reason for the non-equivalence of their behavior in the electrical measurements.

Controllable Fabrication of High-performance Perovskite Single Crystals in Solution toward Efficient X-ray Detection (#2024)

Yu Chen

Beijing Institute of Technology, HaiDian Beijing, China

The financial support from the National Natural Science Foundation of China (No.52373279) and the Beijing Natural Science Foundation (No.4232079).

Abstract

Perovskite single crystals demonstrate great potential in high energy radiation detection applications due to the unique semiconductor properties, while still suffers from uncontrollable growth progress and labile crystal quality. In this paper, we here develop a series of interdisciplinary growth methodologies for fabricating high-quality perovskite single crystals based on the solvent design and additive engineering, achieving high-performance and reliable robustness toward impressive X-ray detection performance.

Abstract

Methylammonium lead tribromide ($MAPbBr_3$, MPB) single crystals are promising candidates for direct-conversion X-ray detection, but their practical use is hindered by ion migration that causes photocurrent drift and baseline instability under continuous X-ray exposure. In this work, a two-dimensional (2D) organic–inorganic hybrid layer is formed on MPB single crystals through a simple solution-dipping process using 4-fluorophenethylammonium iodide (4F-PEAI), and the impact on detector stability is systematically investigated. The 2D-layer formation, controlled through precursor concentration and dipping time, is confirmed by the emergence of a new low-angle XRD peak assigned to a $(4F\text{-}PEA)_2PbX_4$ 2D layered phase, and by a blue shift of the band-edge photoluminescence consistent with surface modification. Surface 2D-layer passivation reduces the dark-current hysteresis, suppresses the photocurrent drift under continuous X-ray exposure, and lowers the in-pulse relative standard deviation, while maintaining linear dose response across the measured dose-rate range. These results demonstrate that surface 2D-layer formation is a practical strategy for suppressing ion migration and improving the operational stability of perovskite single-crystal X-ray detectors.

Highly Radiation-Hard Flexible Perovskite Imaging Arrays for Real-Time Proton Beam Monitoring (#2700)

Yang Zhang, Guangda Niu

Huazhong University of Science and Technology, Wuhan National Laboratory for Optoelectronics and School of Optical and Electronic Information, WuHan, China

Abstract

Real-time proton beam monitoring is crucial for pencil beam scanning in proton therapy, but conventional solid-state detectors suffer from radiation-induced damage and structural rigidity, limiting their in-vivo applications. Building upon the lattice-anchoring dynamic repair mechanism in hybrid perovskites, we developed a highly stable, flexible perovskite thin-film transistor array for real-time proton beam profiling. The detector adopts a p-i-n architecture on a flexible substrate, protected by robust Parylene encapsulation to ensure long-term operational stability. Under 160 megaelectron-volt high-energy proton irradiation, the arrays demonstrated exceptional radiation hardness, maintaining robust operational stability even after accumulating a high fluence of $1.23*10^{10}$ p cm^{-2}. Spatial resolution remained uncompromised post-irradiation, with the spatial frequency at a modulation transfer function of 0.2 showing negligible degradation from about 3.03 line pairs per millimeter.. When deployed in a clinical setup, the TFT array achieved real-time proton beam imaging at a frame rate of 15 frames per second. At a 16-centimeter solid water depth, the measured beam full-width at half-maximum (FWHM) was 8.47 millimeters, perfectly matching the 8.27 millimeters theoretical value predicted by Monte Carlo simulations using FLUKA and Allpix, and it has achieved real-time tracking and prediction of the center of the proton beam. These results validate the immense potential of flexible perovskite TFT arrays for the real-time tracking of the Bragg peak and conformal dose monitoring, offering a transformative dosimetric tool for advanced precision radiotherapy and expanding the practical applications of room-temperature semiconductor detectors.

FAPbBr3 Single Crystal Perovskite Radiation Detector with Embedded Electrode Array Architecture (#2833)

Seán Cardiff, Ganbaatar Tumen-Ulzii, Samuel D. Stranks

University of Cambridge, Chemical Engineering and Biotechnology, Cambridge, UK

This work was supported by the Engineer ing and Physical Sciences Research Council (EPSRC) grant EP/S022139/1- the Centre for Doctoral Training in Connected Electronic and Photonic Systems.

Abstract

Formamidinium lead bromide (FAPbBr3) single crystal perovskites have recently emerged as a key candidate for commercially viable radiation detectors for their high per formance and solution processability at low temperatures. An under-explored consequence of crystal growth from solution is the ability to crystallise around pre-placed structures, enabling detectors with an embedded electrode architecture. This work presents the growth of FAPbBr3 single crystals around a 2×2 array of gold wire electrodes, showing the first demonstration of this device architecture in a FAPbBr3 single crystal radiation detector as a proof of concept. By collecting charge carriers laterally, the charge carrier transit time and trap probability is reduced compared to the planar configuration. Initial charac terisation demonstrated a linear I–V response and sensitivity to X-rays. Future work will scale to a larger array with an increased area targeting γ-ray spectroscopic performance with fast signal pulse rise times.

Abstract

Thallium bromide (TlBr) is a highly promising material for next-generation gamma-ray detectors due to its wide band gap and high stopping power. To realize large-volume and high-performance detectors, it is essential to establish an efficient evaluation method for detector performance. This study aims to investigate the correlation between crystalline structural quality and carrier dynamics in TlBr single crystals. We developed a scanning time-of-flight (TOF) measurement system to evaluate the two-dimensional distribution of electron mobility and trapping characteristics. A 3-mm-thick TlBr wafer was characterized using both EBSD mapping and laser-induced TOF measurements. The results revealed a clear correlation between structural grain boundaries and localized degradations in electron mobility. Furthermore, spatial mapping of the residual charge ratio identified specific regions characterized by high trap densities. Subsequent evaluations of detectors fabricated from these regions showed significantly poor long-term stability. This study provides essential feedback for improving crystal growth processes and establishes a methodology for the quality assurance of compound semiconductor radiation detectors.

Abstract

This study describes the fabrication of the aramid nanofiber (ANF) to produce flexible detectors based on nanomaterials, with short preparation and low surface leakage current. Flexible detectors offer the advantage of achieving improved detection efficiency and efficient use of space with curved surfaces. In previous studies, ANF was used as a porous nanostructured polymer for the fabrication of nanomaterial-based semiconductor detectors. However, it had the issues of a long preparation time and brittleness after drying. To address these issues, we used DMSO containing an aqueous KOH solution in the preparation of the ANF solution. with This reduced the preparation time from one week to two days. Furthermore, we compared the results of ANF coagulation in different soloutions—ethanol (EtOH), acetic acid (AcOH), and a mixed AcOH-EtOH (volume ratio was 7:3) solution—to alleviating the pore collapse of the nanostructure, with the conventional H_2O-based method. The synthesis solution containing PbS quantum dots (about dia. 5 nm) and Te nanorods (130 nm in length), as confirmed by TEM and XRD, was loaded into ANF samples using various coagulation solutions. We confirmed that uniform loading in dpeth occurred in the order of H_2O, EtOH, AcOH, and the AcOH-EtOH mixture. Furthermore, according to the I–V curves, the surface leakage current also tended to decrease in the same order of uniform loading, with a maximum 10,000-fold difference observed between the ANF samples prepared with H_2O (about 100 μA at 10 V) and the AcOH-EtOH mixed solution (about 2 nA at 10 V). Therefore, it was shown that ANF coagulated with the AcOH-EtOH mixed solution remained flexible even after drying, and the uniform embedding of nanomaterials according to depth reduced the surface leakage current.

Abstract

Perovskite materials are promising for low-cost direct X-ray detection, but their integration with thin-film transistor backplanes is limited by porosity, cracking, and poor imaging uniformity. Here, we report a combined strategy of uniform particle dispersion and solution-assisted hot pressing for fabricating uniform $MAPbI_3$ thick films on TFT substrates, where uniform particle dispersion stabilizes slurry dispersion and solution-assisted hot pressing promotes film densification, grain growth, and pore filling. The average particle size of the fabricated devices decreased from 32.07 μm to 15.14 μm, and the standard deviation reduced from 7.3 μm to 4.9 μm. At an electric field strength of 100 $V \cdot mm^{-1}$, the sensitivity reached 3514 $\mu C \cdot Gy_{air}^{-1}\ cm^{-2}$. A prototype $MAPbI_3$-based X-ray flat-panel detector further achieves a spatial resolution of 3.75 lp mm^{-1} at an modulation transfer function of 0.2, together with significantly improved imaging uniformity. This work provides a practical route toward scalable, thin-film transistor compatible perovskite X-ray flat-panel detectors.

Investigation of Metal Oxides as Contact Materials for CdTe X-Ray, Gamma-Ray Detectors (#1816)

Madan Niraula, Masaya Tanimoto, Yamato Ohi, Rikuto Fukuda

Nagoya Institute of Technology, Graduate School of Engineering, Nagoya, Japan

This work was partly supported by JSPS Kakenhi grant (24K15592).

Abstract

CdTe is a well-established semiconductor for high-resolution X-ray, gamma-ray detector. However, its widespread application is limited by high dark current and long-term performance instability. The metal–semiconductor interface plays a critical role in governing these issues, as it strongly influenced by contact metal indiffusion and interfacial reactions. In this work, indium tin oxide (ITO) is investigated as a potential contact material for CdTe detectors to mitigate these limitations. ITO electrodes were deposited on one face of a high-resistivity p-like CdTe crystal by RF sputtering, while a gold electrode was formed on the opposite face by thermal evaporation. The fabricated device showed clear rectifying behavior, with reverse dark currents below 1 nA at 100 V bias for a 3 x 3 x 0.5 mm^3 device, representing a significant reduction compared to similar devices with Au contacts on both sides. Improved gamma-ray detection performance was also observed. Furthermore, the effects of CdTe substrate temperature during ITO deposition and post-deposition annealing on junction formation and detector performance, including dark current, energy resolution, and long-term stability, were systematically investigated.

Transport Properties of CdTe Semiconductor after Laser Ablation (#2458)

Jakub Dřevo, Eduard Belas, Roman Grill, Pavel Moravec, Marián Betušiak

Charles University, Faculty of Mathematics and Physics, Institute of Physics, Prague, Czech Republic

This project is co-financed from the state budget by the Technology agency of the Czech Republic under the SIGMA Programme TACR TQ28000004 Semiconductors4All.The authors gratefully acknowledge Šimon Syrovátka and Vojtěch Kudrna (Hofmeister s.r.o.) for their assistance with laser ablation sample processing.

Abstract

This study investigates the characterization of conductive layers on CdTe semiconductor crystals fabricated via laser ablation. The layers were prepared at both ambient and elevated temperatures, with various ablation parameters evaluated to optimize their quality. Our analysis revealed the formation of conductive layers on the semiconductor surface, exhibiting high hole mobility. These layers were systematically characterized using a suite of electrical and optical techniques, including Hall effect measurements, photocurrent mapping, the Laser-induced Transient Current Technique (L-TCT), and stability tests focusing on time-dependent behavior.

Abstract

Chromium-compensated gallium arsenide (GaAs:Cr) is a highly promising material for spectral X-ray photon counting detectors (PCDs), offering high electron mobility (~4000 cm2/V · s), low K-shell fluorescence (9.2 keV and 10.5 keV), and ultra-high bulk resistivity (~109 Ω · cm). A critical factor governing the high-flux stability of such PCDs is the metal–semiconductor contact. While conventional detectors often rely on Schottky contacts—which trap space charge and cause polarization under sustained irradiation—the ultra-high resistivity of GaAs:Cr enables barrier-free Ohmic contacts. This approach relies entirely on bulk resistance to limit dark current, eliminating

interface charge accumulation and preserving a uniform electric field. In this work, we characterize the wide-bias (−1000 V to 1000 V) dark current–voltage (I–V) behavior of pixelated GaAs:Cr detectors. The devices exhibit highly linear, symmetric responses with distinct Ohmic and space-charge-limited current (SCLC) regimes, confirming high-quality Ohmic contact formation. Furthermore, the extracted bulk resistivity and demonstrated pixel-level uniformity validate the contact integrity required for stable high-flux photon counting applications.

Abstract

A Geant4-based Monte Carlo framework was developed to predict the proton-irradiation stability of FAPbBr3 perovskite. Beyond calculating non-ionizing energy loss (NIEL), the framework records layer-resolved energy deposition across a 2 mm crystal divided into 50 slices. For 70, 100, 150, and 200 MeV protons, the NIEL values are 2.04, 2.01, 1.38, and 1.55*10^-3 MeV cm^2 g^-1, confirming non-ionizing displacement-damage channels. The deposited-energy fractions in the incident-side 0.20 mm are 11.83%, 10.69%, 19.57%, and 14.90%, respectively, following the same order as the measured electrical response: 150 MeV > 200 MeV > 70 MeV > 100 MeV. This agreement indicates that near-surface energy deposition can effectively predict mobility-lifetime product variation and supports the framework as a screening tool for perovskite radiation stability.

Abstract
The effect of the Low Earth Orbit (LEO) environment on future high energy instrument sensors is essential to optimize their performance, by minimizing orbital background noise. In the framework of the CNES-ESA European Material Ageing program (EMA), the ageing effects on critical components of a Laue lens telescope in the LEO space environment is investigated. Since more than a decade, the group has been developing CZT drift strip sensors to meet the stringent requirements of a Laue lens focal plane detector for high-energy photons. As part of the EMA proposal, two simplified samples of drift strip CZT detectors were exposed to outer space on the CNES Bartolomeo external platform of ISS for more than 12 months. The objective was to test the robustness and reliability of the surface passivation and metallization processes in the LEO space environment. The samples were taken down to earth on February 27. In this work, we report on the results of the simulations we carried out accounting for possible damages to the detector properties due to agents as oxygen and high energy ions. Also, preliminary measurements on the detectors come back from space will be shown.

Development of a Compact CdTe-Based Gamma Spectroscopy System with Dual-Side Readout for High-Resolution Gamma Imaging (#1117)

Siyao Chang, Setsuo Sato, Yuki Mitsuya, Hiroyuki Takahashi

The University of Tokyo, School of Engineering, Tokyo, Japan

Abstract

We developed a compact CdTe-based gamma-ray spectroscopy system with a dual-side readout architecture for high-resolution gamma imaging. The system is designed for pixelated Schottky CdTe detector arrays. Cathode pixels at the same relative position across multiple detector chips are multiplexed, while the anode of each chip is read out independently. This configuration reduces the number of readout channels and system complexity while preserving energy information from the anode side and position information from the cathode side.

The system integrates custom JFET-input charge-sensitive preamplifiers and a waveform-sampling data acquisition system based on AFE5801 chips, enabling measurement of pulse height, risetime, and waveform information.

To evaluate the feasibility of the proposed method, spectral measurements were performed using a 2 × 1 CdTe detector array operated at +650 V with sealed ^{22}Na and ^{137}Cs sources. A 1 μs coincidence time window was applied to match the anode and cathode signals. Calibrated energy spectra were obtained from both sides. The anode signal showed slightly better energy resolution and was used as the primary signal for energy measurement, while the cathode signal can provide position information. After applying risetime selection, energy resolutions of 3.61% at 511 keV and 3.20% at 662 keV were achieved. These results demonstrate the feasibility of the proposed dual-side merged readout architecture.

A 5 × 5 CdTe detector array has also been assembled, and further verification experiments are in progress.

Abstract

Three-dimensional position-sensitive CdZnTe (3D-CZT) gamma-ray detector systems provide compact gamma-ray spectroscopy with 3D position sensing. Achieving high performance requires event-by-event energy and position reconstruction to compensate for charge loss, gain variation, and response nonlinearity. Such reconstruction calculations are typically performed on a powerful CPU. To reduce power consumption and minimize system

footprint, we propose implementing the reconstruction in an application-specific integrated circuit (ASIC). In this work, we focus on single-pixel event reconstruction, integrating depth and nonlinearity corrections along with a sub-pixel position calculation. This ASIC is implemented in TSMC 65 nm CMOS technology and is designed to interface with a DAQ-DSP back-end ASIC and four H3DD-UM front-end ASICs. Preliminary results demonstrate the feasibility of an event reconstruction ASIC with an area of 2.43 mm^2. This development represents a key step towards the development of more compact 3D-CZT systems.

Abstract

XRPIX is a silicon-on-insulator (SOI) CMOS pixel detector developed for next-generation X-ray astronomical observations. An X-ray camera, SUIM (Soipix for observing Upper atmosphere as Iss experiment Mission), is our first space mission employing XRPIX and is planned for launch to the International Space Station (ISS) in 2026. Thermal analysis of the SUIM instrument indicates that the camera housing may reach temperatures as high as +60°C in orbit, making it essential to verify XRPIX performance under elevated temperature conditions. The primary concern under such conditions is the degradation of spectroscopic performance due to increased dark current. Spectroscopic measurements using ^{241}Am were conducted over a temperature range from −30°C to +70°C, with a periodic reset of 100 µs applied to suppress dark current accumulation during integration. Only minimal degradation was observed, confirming that the periodic reset scheme effectively maintains good spectroscopic performance even at +70°C. The gain decreases at a rate of −0.132 µV e^{-1} $°C^{-1}$, which can be corrected through gain calibration. These results demonstrate that XRPIX maintains sufficient spectroscopic performance at least up to +70°C, indicating that its performance is also adequate for use in the SUIM instrument.

Abstract

TlBr is a promising compound semiconductor material for gamma-ray detectors[1] because of its wide bandgap, high-Z constituents, and high density, which enable room-temperature operation and high detection efficiency. However, because the hole mobility in TlBr is significantly lower than the electron mobility, single-polarity charge sensing techniques are required to achieve high energy resolution. In this study, a zero-grid-bias operation in a coplanar-grid electrode structure for TlBr gamma-ray detectors was investigated. Unlike conventional coplanar-grid detectors, the proposed structure operates without a bias voltage between adjacent grid electrodes, which may reduce leakage current.

A conventional comb-shaped electrode structure was evaluated experimentally and through simulations using a Cs-137 source. The simulation results reproduced the experimental pulse-height spectra well. In addition, pulse-height correction using the cathode-to-anode pulse-height ratio improved the energy resolutionTo further improve detector performance, the weighting-potential distribution inside the detector was analyzed, and a spiral-shaped electrode structure was proposed to suppress spatial nonuniformities in the weighting potential. Simulations indicated that the proposed spiral-shaped electrode structure suppressed spatial variations in the weighting potential between adjacent anodes, leading to improved energy resolution after correction. These results suggest that the proposed spiral-shaped zero-grid-bias coplanar-grid electrode structure is a promising approach for large active volume and high-resolution TlBr gamma-ray detectors.

Abstract

This study investigates the spectral performance of a unipolar charge-sensing amorphous selenium detector using Monte Carlo simulation and compares its response with that of a conventional amorphous selenium detector. The unipolar charge-sensing architecture mitigates the limitations associated with poor electron mobility and deep electron trapping in amorphous selenium by promoting hole-dominated signal formation. Both unipolar charge-sensing and conventional detector structures were simulated for a 20 μm pixel pitch under an average electric field of 8 V/μm. The simulated full-width at half maximum energy resolution was 8.02 keV for the unipolar charge-sensing detector, compared with 21.32 keV for the conventional detector. These results demonstrate that the unipolar charge-sensing architecture substantially improves the spectral performance of amorphous selenium detectors by suppressing depth-dependent signal variations and reducing sensitivity to electron trapping.

Abstract

We report on the characterization of the Timepix4 hybrid pixel detector with a Si sensor under exposure to heavily ionizing particles. The device was configured sequentially in three gain modes: logarithmic (log), high, and low. Previously developed methodology of pixel's energy calibration beyond calibration with X- and γ-rays was adopted and applied to Timepix4 data. It uses the protons with energies in the range from 500 -- 2000 keV. Saturation of the pixel's energy response was observed at 1057, 1244, and 2030~keV in the low, high, and log gain modes, respectively. In a laboratory experiment, the detector was irradiated with α-particles from a ^{239}Pu^{241}Am^{244}Cm source, even higher energy α-particles were obtained from naturally occurring radon progeny decays recorded over several weeks of continuous operation. Both measurements yielded an energy resolution of about 2.5\%. The capability of Timepix4 for relativistic ion beam decomposition was investigated within fragment beams at the Super Proton Synchrotron (SPS) at CERN. A spectrum stripping technique based on iterative Landau curve fitting was applied to the measured energy-loss spectra, enabling ion charge identification up to Z = 10 at a track inclination of θ = 60 deg. with respect to the sensor normal.

Investigation of Gain Instability of a 3-D CdZnTe Detector (#2768)

Matthew Granados, Yuefeng Zhu, Zhong He

University of Michigan, Ann Arbor, USA

Abstract

CdZnTe (CZT) detectors require stable calibration parameters for optimal spectroscopic performance. However, certain pixels exhibit random gain variation during or between measurements, complicating calibration and degrading detector performance. Digital ASICs allow for readout of event waveforms in a CZT detector exhibiting gain instability. Th-228 and Cs-137 measurements were utilized to characterize the gain instabilities, revealing a

decrease in the anode amplitudes proportional to the incident energy. Analysis of the neighbor pixel-anode waveforms reveal abnormally high tail amplitudes in the four side neighbors which exceed expectations based on the Shockley-Ramo theorem. The corner neighbors experience noticeable smaller increases in tail amplitudes. Sub-pixel position analysis demonstrates that the tail amplitude increase is not proportional to the neighbor signal amplitude. These findings suggest that the observed gain instability could be caused by issues with capacitance in the system rather than anomalous charge movement. Ongoing work aims to verify the cause of the shift and if the anode deficit can be entirely explained by the differences in the neighbor waveform signals.

Abstract
In the present work, we study the MiniPIX Timepix hybrid pixel detectors with silicon sensors of two different thicknesses and their response to high energy protons. Thermally stabilized detectors measured protons of five energies, 400, 700, 1000, 1400 and 1800 keV in vacuum. During the measurements, a bias scan was performed to investigate the efficiency of collection of charge carriers generated by the protons. With increasing reverse bias, the signal from the detector grew until it saturated. The 300 um thick detector required an electric field generated by a reverse bias of 30 to 40 volts for effective charge collection. A detector with a thicker 500 um sensor required approximately 70 V bias for complete charge collection when registering 400 keV protons and a gradually higher bias of up to 100 V in the case of 1800 keV protons. The much larger bias for a complete collection of the charge generated by protons in a thick detector is in correlation with the theory, where the semiconductor depleted region thickness increases proportionally to the square root of applied reverse bias.

Abstract

The Timepix family of pixel detectors provides high spatial resolution together with per-pixel spectroscopic response, allowing event-by-event analysis of radiation interactions through deposited energy and cluster morphology. In fast neutron fields, the detector response is indirect and is produced mainly by secondary particles generated in the sensor and surrounding materials. This work focuses on fast-neutron-induced tracks measured with a Timepix3 detector equipped with a 300 µm silicon sensor at the Van de Graaff laboratory of IEAP CTU in Prague, using neutrons produced trough D–T reaction, in the range of approximately 15–17.5 MeV. The data were processed using TraXEngine [1] and further evaluated through selected spectral and morphological cluster parameters. The selected parameters were analyzed in two- and three-dimensional parameter spaces, where high-density regions corresponding to characteristic event groups were identified. Based on these regions, five parameter-based classes were defined: high-energy ion-like events, low-energy ion-like events, a transition region toward electron-like events, photon-like events, and electron-like events. The developed parameter-space analysis shows that combinations of spectral and morphological parameters can be used to separate components of a fast-neutron-induced mixed radiation field and can support future automated particle-recognition methods.

This work was financially supported in part by the National Key Research and Development Program of China under Grant 2024YFF0507800.

Abstract

Direct-conversion X-ray flat-panel detectors are attractive for high-resolution and low-dose imaging compared to indirect conversion. However, conventional passive pixel sensors (PPS) without in-pixel gain are commonly used in direct-conversion detectors, causing low signal-to-noise ratio under low-dose exposure. In this work, a compact two-transistor active pixel sensor (2T-APS) with in-pixel current amplification based on amorphous indium-gallium-zinc-oxide (a-IGZO) dual-gate TFTs is proposed for low-dose direct-conversion X-ray imaging. The proposed pixel employs two subthreshold-biased dual-gate TFTs to realize logarithmic–exponential signal processing, enabling electrical tuning of the operating point and sensitivity.

A 512×256 2T-APS array was fabricated using an a-IGZO dual-gate TFT process with a pixel pitch of 75 μm×75 μm. Pixel-level characterization further demonstrated amplification of pA-level input currents, achieving a representative current gain over 10^3. The fabricated array was integrated with a perovskite layer to realize X-ray imaging. At the tube voltage of 50 kV, images acquired with tube currents from 0.5 mA to 2.0 mA clearly visualized the object outline. These results validate the feasibility of the proposed a-IGZO dual-gate 2T-APS pixel for low-dose, high-sensitivity direct-conversion X-ray flat-panel detectors.

Abstract

Simultaneous multi-nuclide imaging is a key challenge in nuclear medicine, promising benefits such as improved diagnostic accuracy, reduced examination frequency, and elimination of physiological variations between scans. However, conventional imaging systems such as positron emission tomography (PET) and single-photon emission computed tomography (SPECT) are based on fundamentally different principles, making their integration into a single system technically difficult. To address this, we have proposed and developed a Compton-PET camera that enables simultaneous visualization of PET and SPECT nuclides using PET and Compton imaging, respectively. In our previous implementation, the system employed GAGG scintillators as absorbers, but their limited energy resolution (11–15% FWHM above 100 keV) degraded the Compton imaging performance. Thallium bromide (TlBr) semiconductor detectors have been shown to offer both high energy resolution, such as 2% FWHM at 662 keV, and high time resolution, including 511 ps via Cherenkov photon detection, making TlBr a promising sensor material for improving Compton-PET performance. Based on these advantages, we developed a new multi-pixel TlBr semiconductor detector by bonding a TlBr crystal to a self-triggering, energy-resolving pixel application-specific integrated circuit (ASIC). We plan to present the results of I-V characteristic measurements and evaluate detector performance through energy spectrum measurements and time resolution analysis using radionuclide sources.

Readout Electronics of SPECTRE CZT detector (#2525)

Michela Greco[1,2], Vincenzo Monaco[1,2], Federico M. Melendi[4,3], Damanio Cabiati[1], On behalf of SPECTRE Collaboration

[1] INFN, -Torino, Torino, Italy; [2] University of Turin, Physics Dept., Torino, Italy; [3] University of Ferrara, Physics Dept., Ferrara, Italy; [4] INFN, -Ferrara, Ferrara, Italy

Abstract

The INFN SPECTRE (Single Photon Emission Computed Tomography Readout Electronics) project aims to design, assemble, and characterize a complete detection module based on CZT sensors for medical applications. As the demand for SPECT systems with higher spatial resolution, energy resolution, and sensitivity continues to grow, there is an increasing need to develop high-performance CZT detectors with small pixels and corresponding high-speed readout electronics [1,2].

For readout, SPECTRE uses electronics developed for a high-capacitance gas detector (CGEM@BESIII, IHEP, Beijing [3]): the TIGER (Torino Integrated GEM Electronics for Readout) ASIC for on-detector electronics and the off-detector FPGA-based GEMROC module for power and data processing [4]. TIGER is a mixed-signal chip with 64 channels on an area of 5 × 5 mm². Each channel has a complete readout chain with amplification, signal conditioning, and discrimination, as well as a data payload containing the time and charge information for each event. TIGER is versatile for the readout of radiation sensors up to 50 fC and for high rates up to 70 kHz. The TIGER/GEMROC readout circuit is compact, modular, scalable, and highly customizable. In typical CZT applications today, spectroscopic systems operate at rates of about 1 kcps/mm² because extracting energy information requires more processing time [5]. However, our system can acquire each sensor pixel at a rate of up to 70 kHz, or approximately 16 kcps/mm².

In this presentation, we will cover all phases of the project to date, including CZT sensor and electronics simulation with the Allpix Squared package [6], based on Geant4, current-voltage characterization of the CZT sensors, system design and construction, assembly of four modules onto an adapter board, and initial system characterization using X-rays.

Abstract

Photon-counting computed tomography requires readout ASICs with high count-rate capability and reliable spectral performance under clinical X-ray flux. In this work, a peak-finding ASIC for GaAs:Cr photon-counting detectors is presented. The prototype ASIC contains a 9 × 12 pixel array with a pixel pitch of 341 μm × 368 μm. Each pixel integrates a charge-sensitive preamplifier, shaper, peak-finding circuit, five energy bins, threshold DACs, and counters. The peak-finding circuit captures the amplitude of signal peaks, improving counting capability under high-flux conditions. Electrical measurements demonstrate reliable counting performance beyond 30 Mcps/pixel. After coupling with a GaAs:Cr sensor, X-ray measurements showed clear tungsten characteristic peaks, confirming the energy-discrimination capability of the detector module. These results demonstrate the potential of the proposed ASIC for high-flux GaAs:Cr-based PCCT detectors.

Abstract

Photon-counting detectors (PCDs) with high-Z sensors are widely used for spectroscopic X-ray imaging in medical, security, and industrial applications. Hybrid PCDs can be coupled to different semiconductor sensors (Si, CdTe, GaAs), tailoring the assembly to the application. CdTe is the sensor of choice for energies above 50 keV, given its higher absorption efficiency compared to Si. The Timepix3 is a pixelated hybrid PCD that records each individual photon interaction in the sensor, providing the time-over-threshold (energy) and time-of-arrival of each event at fluxes up to 40 MhitsHits/cm^2/s. The spectral resolution of CdTe-Timepix3 assemblies degrades with sensor thickness, and the relative weight of front-end electronic noise and sub-threshold charge-sharing losses has not yet been quantified at 55 µm pitch. An empirical equivalent-noise-charge (ENC) model exists for Si-Timepix3 but, to our knowledge, has not been reported for CdTe at this pitch. This work addresses this gap by measuring the front-end ENC of three CdTe-Timepix3 assemblies (1 mm, 3 mm, and 5 mm sensor thickness) from internal test-pulse scans, fitting an empirical ENC model with the detector capacitance estimated from per-pixel geometry, and decomposing the photopeak FWHM at the ^{241}Am (59.5 keV) line into Fano, front-end, and sub-threshold contributions. A Si-Timepix3 of the same ASIC family is included as a cross-check for the front-end term. The result is a quantitative basis for predicting CdTe-Timepix3 spectral performance as a function of sensor thickness on this ASIC.

Abstract

In semiconductor radiation detectors such as silicon (Si) and silicon carbide (SiC) the sensor bias determines the radiation sensitive volume. Varying the sensor applied bias can thus significantly change and even distort the detector response, sensitivity and spectral-tracking properties. These effects can be studied and described when the sensor is bump-bonded to the Timepix3 detector which provides particle counting response, high-granularity imaging detection and spectral-tracking ability to single particles. These properties make possible to analyze and resolve particle-type events which is useful for mixed-field decomposition. In this work we examine and experimentally investigate the response of the SiC Timepix3 detector to well-defined fast neutrons to quantify and analyze the changes induced by varying the sensor applied bias voltage. The main effects are further decreasing the detection efficiency, which is overall low (≤ 1%), and only partly reducing the spectral-tracking resolving power to particle-type discrimination.

Abstract

This study presents an experimental and computational framework for gamma-ray imaging using a position-sensitive Cadmium Zinc Telluride (CZT) detector combined with deep learning–based reconstruction techniques. A GDS-100 CZT detector with an 11 × 11 pixelated anode matrix was irradiated using a tightly collimated 662 keV Cs-137 gamma-ray beam scanned across the detector surface with 1 mm step size. Detector waveforms were used to train a compact ResNet-based convolutional neural network capable of reconstructing higher-resolution spatial information by mapping 11 × 11 detector inputs to 22 × 22 outputs. Kernel density estimation (KDE) analysis of reconstructed events shows that the predicted interaction positions remain strongly localized around the true coordinates, demonstrating accurate spatial learning. Average spatial spreads of σx = 1.375 mm and σy = 1.398 mm, together with positional deviations below 1 mm, indicate stable and nearly symmetric localization performance. Although edge and corner regions exhibit slightly broader distributions due to detector-related physical effects, the reconstructed interaction densities remain well confined around the true positions. Overall, the results demonstrate that deep learning–based CZT signal analysis can significantly improve spatial reconstruction performance in semiconductor gamma-ray imaging systems.

Abstract

Reliable radioisotope identification with handheld instruments remains challenging due to limited detector resolution, shielding, low counting statistics, and variable background conditions. We present a convolutional neural network algorithm for automated multi-isotope identification from gamma-ray spectra acquired with low-resolution detectors. The algorithm is trained using an optimized synthetic spectral library of 48 radionuclides and evaluated using measured data acquired under controlled shielding, signal-to-noise ratio, and count-rate conditions. Results show near-perfect identification accuracy for moderate to high signal-to-noise ratio regimes and for low to high statistics. At low signal-to-noise ratio the algorithm is still able to recognize some radionuclides with decent accuracy. These results demonstrate that the method provides a practical and scalable solution for real-time isotope identification in nuclear security and radiation detection systems.

In-situ high-resolution gamma spectroscopy for characterization of radiological environmental sites. (#2318)

Bertrand Rossé, Ludivine Fevre, Maxime Allerme, Pascal Chotard

CEA, DAM, DIF, F-91297 Arpajon, France

Abstract

In the context of in-situ radiological characterization of sites (natural or artificial radioactivity) and for the dismantling of nuclear installations, high-resolution gamma-ray spectrometry is a powerful tool to both identify and quantify gamma-emitters. This technique makes it possible to better define the state of radiologically polluted soils without having to collect samples. To perform mapping of large areas (a few hundred square meters) and to detect radiological hotspots, we first use a 2''x2'' NaI(Tl) scintillator probe (Mirion® SG2R) at 20 cm from the ground in pedestrian mode, called C.R.E.M.P (Caractérisation Radiologique En Mode Piéton, radiological characterization in pedestrian mode). Then, for each particular points, high-resolution gamma spectrometry is performed with an HPGe Ortec® DETECTIVE-X. To obtain a reliable transfer function, the absolute efficiency of the detectors must be known. We therefore used our radiological characterization platform located at CEA/DAM Ile de France. Thanks

to these measurements, a geometric model of the HPGe detector was developed and optimized using the MCNP Monte Carlo simulation code taking into account real position and shape of the germanium crystal including mechanical supports and dead layers. To validate the model, experiments on radiologically marked standard soils were performed. Extrapolated data from MCNP simulations make it possible to obtain the transfer functions for each detected radionuclide. The whole method, measurements and simulations will be described.

Gamma Spectroscopy Analysis and Benchmarking of Nuclear Fuel for Next Generation Reactor Designs (#3247)

Daryl T. Giglio, Tommy V. Holschuh, Scott J. Thompson, Jay D. Hix, David L. Chichester, Jeff Sanders

Idaho National Laboratory, Idaho Falls, USA

Abstract

This paper contains the findings associated with the collection of gamma spectroscopy of a variety of fuel types being utilized in the deployment of the next generation of nuclear reactors. Gamma spectroscopy of TRISO fuel types at HALEU levels of enrichment were collected and analyzed prior to installment in their respective reactor designs. Preliminary measurements of these fuels establish a strong baseline that serve as important experimental data points for simulation validation and monitoring fuel characteristics that are underexplored in next generation reactor designs such as burnup rates, and fuel stability (physical, chemical, performance).

In addition, the established baseline also serves as an important benchmark for quality assurance and nuclear nonproliferation by providing reference spectrum for archiving purposes in a nuclear fuel landscape that is rapidly expanding. This ensures enrichment reporting is accurate in the event of fuel mixing/reprocessing prior to reactor loading.

Abstract
Simulation of Photon Counting Detectors (PCD) is essential to optimize detector design and to assess detector response for photon counting CT. In this work, synchrotron measurements performed with the new PCD tiles, developed by Detection Technology (DT) are compared to simulated data. The detector prototype is a pixelated array of CdTe and CZT pixel with 350 µm pixel pitch. Each pixel has 6 energy thresholds. Measurements were carried out at the European Synchrotron Radiation Facility (ESRF) using pencil beam scan to study charge-sharing and fluorescence escape. The experiment was reproduced in a simulation framework that encompasses physics interaction within the sensor, charge generation, drift, and diffusion and Coulomb repulsion. The comparison focuses on counts of distribution across pixel positions and single pixel spectral response. Results show a good agreement for central pixel irradiation, but discrepancies are observed near pixel boundaries. The assessment of the modeling for interpixel irradiation is currently under study.

Characterization and Compensation of Radiation-Induced Leakage Current in CdTe/CZT Detectors Under High-flux X-ray Irradiation (#2377)

Xinchi Ran, Zhi Deng, Haibo Luo, Hanzhe Dong

Tsinghua University, Beijing, China

This work is supported by the Beijing Natural Science Foundation under Grant L242002 and the State Key Program of National Natural Science of China under Grant 62031020.

Abstract
Radiatio-induced leakage current has been found in ohmic CdTe/CZT detectors under high-flux X-ray irradiation scenario such as photon-counting X-ray CT and new generation light sources. Slowly evolving radiation-induced leakage current that compromises signal stability. In this work, we experimentally characterize the dynamic behavior of this leakage current using step-irradiation and rapid-chopping measurements on a custom 32×32 pixel

CdTe detector module. The results reveal a two-timescale response consisting of a fast photocurrent component and a slow, history-dependent leakage component that increases approximately exponentially during irradiation and decays over minutes after beam-off. This behavior is attributed to trap occupancy dynamics that modulate carrier injection at the contacts. A first-order exponential model is proposed to describe the temporal evolution, and a recursive deconvolution framework is explored for signal correction. However, observed nonlinearities and flux/history dependence indicate that a linear time-invariant (LTI) assumption is insufficient, suggesting the need for a more general nonlinear model. These findings provide insight into the instability mechanisms of Ohmic CdTe detectors and offer experimental support for the development of improved dynamic correction strategies for high-flux X-ray imaging applications.

Abstract

CdTe Timepix3 based instruments are an excellent option to perform fine Compton gamma-ray polarimetry. Its high pixelization level (55×55 μm^2) allows to maximize instruments modulation factor and to deliver the higher polar angular resolution in the soft gamma-ray domain. This level of performance is especially important for future gamma-ray astrophysics’ telescopes, since high-energy polarimetry is still a domain with a vast research potential. Timepix3 can be operated in two modes: frame mode and data-driven mode. In data-driven mode each interaction full detection data is available: pixel position (x and y), energy and time. In the frame mode only position (x and y) and energy are available for a given time interval, during which all interactions are integrated in a single frame. However, in this mode less intensive front-end electronics’ processing capacity is required leading to substantial lower power consumption. This is an advantage that can be decisive for applications where high sensitive polarimetry must be performed in low electric power platforms, such as cubesat platforms. An experimental set of measurements with a CdTe Timepix3 operating in frame mode was performed at ESRF under a ~99% polarized

200 keV beam. A Q polarization modulation factor of 0.71 ± 0.014 was obtained, proving that under certain conditions and constraints, frame-mode polarimetry is not only a valid method but also a performant one.

Abstract

This work compares the imaging performance of a GaAs photon-counting detector (PCD) and an energy-integrating detector (EID) under various photon-flux conditions. The detectors were characterized using the modulation transfer function (MTF), noise power spectrum (NPS), and detective quantum efficiency (DQE), and were evaluated under similar effective spatial-resolution conditions. An NPS-based noise prediction model was then used to estimate the image standard deviation as a function of photon count. The results show that the GaAs PCD and the resolution-matched EID exhibit comparable frequency-domain performance and image quality under the reference photon-flux condition. At low photon flux, however, the PCD shows a markedly lower predicted noise level. Finally, phantom imaging experiments further confirm that the PCD provides lower background fluctuations and clearer structural visibility under low-flux conditions. These results demonstrate the noise advantage of GaAs photon-counting detectors for low-flux X-ray imaging.

Abstract

$CsPbBr_3$ is a perovskite room-temperature semiconductor crystal, with properties for high-resolution gamma-ray detection. This material has been fabricated in large volumes, with detectors up to 12 mm thick demonstrated to remain stable for up to 4 months under continuous bias, achieving energy resolutions of 1.1%-1.6% FWHM at 662 keV. This research employs depth-of-interaction analysis on a 12 mm-thick pixelated detector to investigate how optimizing digital pulse shaping parameters as a function of interaction depth and pixel electrode can improve energy resolution. Rather than applying a uniform set of shaping parameters across all events, each waveform is processed independently, allowing shaping to be tuned to the charge-transport characteristics specific to each depth bin and pixel pair. Two optimization methods are compared: a Linear 1D approach, in which rise time and flat-top time are constrained to be equal, and a Grid 2D approach, in which both parameters are varied independently across a wider search space. Our results show that both depth-dependent methods consistently outperform uniform shaping across all drift times. The 2D grid method achieves lower energy resolution than the 1D method but at a significantly higher computational cost (up to an order of magnitude slower). Using 1D optimization, per-pixel energy-resolution improvements of 4.1% to 15.4% were observed, with a best achieved resolution of 0.65% FWHM at 662 keV for near-pixel-side events, representing an improvement over previously reported thinner detectors while maintaining comparable stability.

On Technological Aspects In The Development Of Perovskite Gamma Radiation Detectors (#1472)

Normunds Grundmanis[1], Vladimir Gostilo[1], Aleksandr Lupilov[1], Alan Owens[2]

[1] Baltic Scientific Instruments, Riga, Latvia; [2] Czech Technical University, Institute of Experimental and Applied Physics, Prague, Czech Republic

Abstract

This paper outlines the technological steps and methods used to manufacture perovskite semiconductor radiation detectors and compares them with those used in the manufacture of other semiconductor materials, such as HPGe, Si, CZT, CdTe, and TlBr. We analyse the problems and limitations arising when implementing these technologies at this early stage of perovskite detector development. We examine and critique the technologies involved in crystal growth and processing; for example, mechanical (cutting, grinding, polishing...), chemical (etching, washing...), contact deposition and patterning (masking, photolithography) as well as the welding of contacts and micro assembly of detector crystals.

Applying the processes described above to $CsPbBr_3$ crystals of dimensions of 5´5´3 mm^3, we have manufactured a number of radiation detectors with different contact architectures - a planar contact structure, a planar structure with a guard ring and a ring-electrode type structure. The detectors provided FWHM energy resolutions of less than 1% at 662 and 1332 keV (0.79% and 0.86%, respectively) with a peak to Compton ratio of 11, The FWHM energy resolutions at 59.5 keV, 122 keV and 5.9 kV were 2.7 keV (4.5%), 3.9 keV (3.2 %) and ≤2.6 keV, respectively.

Abstract

Metal-halide perovskites are promising low-cost semiconductors for photon-counting X-ray imaging. However, their temporal response is often hindered by ion migration induced field screening, which can lead to an underestimation of charge carrier mobility. Here, charge transport is studied in $CsPbBr_3$single-crystal detectors using time-of-flight technique and ^{241}Am (60 keV) gamma-counting spectroscopy under direct-current (DC) and alternating-current (AC) bias. In DC operation, polarization effects restrict the extracted hole mobility to ~36 $cm^2V^{-1}s^{-1}$. Applying AC bias suppresses ionic accumulation and reveals substantially higher hole mobility, reaching up to ~560 $cm^2V^{-1}s^{-1}$. Gamma counting under AC operation preserves energy resolution (~10–11%) while accelerating charge collection: the mean response time decreases from ~460 ns (DC) to ~110 ns (AC). These results show that alternating biasing mitigates ion migration induced field distortion and enables perovskite detectors to approach the response speeds required for fast photon counting.

Abstract

Solution-grown lead halide perovskites are promising materials for next-generation radiation detectors. Inverse temperature crystallization (ITC) growth is widely used to obtain large crystals within a relatively short time. However, the rapid increase in supersaturation during heating promotes spontaneous nucleation, leading to compositional inhomogeneity and elevated defect density. To address this limitation, we investigated the growth of $MAPbBr_3$ single crystals using a slow solvent evaporation-induced crystallization method performed at a controlled, constant temperature near room temperature. X-ray diffraction confirmed the formation of high-quality single crystals with improved crystallinity compared to our standard ITC-grown crystals. Detectors fabricated in an Au/$MAPbBr_3$/Cr planar configuration exhibited reduced dark current and enhanced X-ray sensitivity relative to

devices based on ITC-grown crystals. These results demonstrate that this growth strategy provides a viable pathway to improved crystal quality and device performance.

Abstract

Low-dose diagnostic X-ray imaging requires detector materials that combine high stopping power, low electronic noise, fine spatial resolution, and stable operation under clinically relevant X-ray energies. Cadmium telluride currently provides this performance in direct-conversion imagers, but its cost and crystal-growth constraints limit scalability. We report direct conversion detectors working in photovoltaic mode based on solution-grown mixed-cation methylammonium-formamidinium lead triiodide single crystals. The crystals were grown with controlled thicknesses up to 1 mm on charge-selective contacts and patterned indium tin oxide arrays. Optical and X-ray detection characterization shows millimeter-scale charge extraction without an externally applied field, with electron mobility-lifetime products up to 0.17 $cm^2 V^{-1}$ and diffusion lengths of 3.5 mm. The devices achieve single-photon sensitivity and detective quantum efficiency above 90% at 60 keV, while the same growth route enables conformal integration into 40 µm-pitch linear arrays with spatial resolution up to 19-line pairs per millimeter. The detectors also maintain a stable response over up to two years of intermittent operation and storage. These results indicate that solution-grown perovskite single crystals can approach cadmium telluride-level low-dose imaging performance while retaining a scalable low-temperature materials platform for medical and industrial X-ray imaging.

Abstract

We present a scalable and calibrated proton dosimetry platform based on flexible 2D perovskite (PEA_2PbBr_4) thin films, enabling high-resolution beam profiling in clinically relevant conditions. The devices consist of solution-processed thin films deposited on 75 μm Kapton substrates and operated as two-terminal coplanar detectors. Their response has been characterized under therapeutic proton beams (70–200 MeV), showing stable operation, good radiation tolerance up to 20 Gy, and a linear dependence of the collected charge on the total dose. The current response exhibits a reproducible sublinear dependence on dose rate, enabling the definition of calibration protocols. The scalability of the technology is demonstrated through multipixel linear arrays composed of up to 28 devices arranged side-by-side, showing good uniformity with pixel-to-pixel variations below 25% in sheet resistance and 15% in calibration parameters. After calibration, the system enables accurate reconstruction of transverse proton beam profiles in agreement with nominal beam shapes. A key feature of these detectors is their angular-independent response (<2% variation up to 90°), which enables operation in an edge-on configuration and a transition from pixel-pitch-limited to thickness-limited spatial resolution. This concept is extended to a stacked pixel-on-pixel multipixel architecture for high-resolution beam profiling (77 μm). Finally, the devices have been validated in an anthropomorphic phantom under clinical 200 MeV proton irradiation, demonstrating the capability to discriminate beam position shifts and reconstruct dose profiles consistently with radiochromic film and commercial dosimetry measurements. These results highlight the potential of flexible 2D perovskite detectors as a versatile platform for scalable, high-resolution, and real-time proton beam dosimetry.

Phase-Pure Orthorhombic $CsPbBr_3$ Perovskite Materials for Low-Lag, Ultrahigh-Resolution Direct X-ray Detectors (#3093)

Amlan Datta, Brandon Dunham, Shariar Motakef

CapeSym, Inc., Research and Developement, Natick, USA

This research was supported by the U.S. National Institutes of Health under award R44EB038123.

Abstract

Room-temperature direct-conversion X-ray imagers require sensor materials that combine high stopping power, efficient charge transport, spatially confined charge collection, and stable temporal response. We report an all-inorganic perovskite detector platform in which phase purity of cesium lead bromide ($CsPbBr_3$, CPB) is used as the central materials control parameter. Low-impurity, spectroscopic-grade CPB crystals were produced by purification and optimized Bridgman growth, milled to nanopowder, and blade-coated into dense sensor films on active-pixel readout arrays at temperatures compatible with backplane electronics. X-ray diffraction of both precursor crystals and sensor films showed the stable orthorhombic Pnma phase with characteristic reflections, indicating preservation of phase through crystal-to-powder-to-film conversion. In contrast, unoptimized starting material contained a $CsPb_2Br_5$ tetragonal secondary phase, generated nonuniform slurries and aggregate-rich films, and produced degraded X-ray images due to interpixel charge sharing. The optimized CPB sensors demonstrated linear response to 30 keV X-rays, sensitivity of 55,400 μC Gy_{air}^{-1} cm^{-2} at 0.5 V/μm, a limit of detection of 417 pGy_{air} s^{-1}, and a hole mobility-lifetime product of 8.0×10^{-4} cm^2/V. Phase-pure CPB also produced low residual lag, reducing detector lag from 8.9% to 1.1%, while enabling 6.9 lp/mm at 20% modulation transfer function on a 100 μm-pitch amorphous-silicon array and 20 lp/mm on a fine-pitch CMOS readout. These results identify phase-pure orthorhombic CPB as a scalable room-temperature semiconductor for low-lag, high-sensitivity, high-resolution X-ray imagers.

Abstract

The performance under X-rays (with energies up to 40 keV) of self-powered detectors with a submicrometric metal-halide-perovskite ($FAPbBr_3$) active layer was systematically investigated as a function of the $FAPbBr_3$ film thickness, ranging from 180 to 840 nm. Results show that an intermediate thickness of 710 nm represents the best trade-off among sensitivity (up to 571.07 μC Gy^{-1} cm^{-2}), limit of detection (down to 39.55 nGy s^{-1}), linearity with the dose-rate, and stability over time (signal fluctuations <1% within 1 h of continuous irradiation).Very significantly, it is here shown that, in the case of submicrometric $FAPbBr_3$ film-based X-ray detectors, a better performance is not necessarily connected to a larger thickness; the benefits of a better X-ray absorption are indeed nullified by a drastic decrease of the photoconductive gain, due to increased interface charge accumulation and enhanced recombination.

Abstract

The organic hybrid perovskite $FAPbBr_3$ shows great potential as a radiation detector, particularly due to its synthesis using cost-effective room-temperature solution-based growth processes. In this paper we report on recent improvements in the quality of solution-grown $FAPbBr_3$ single crystals using a sulfonic zwitterionic ligand 3-(Decyldimethylammonio)-propane-sulfonate inner salt (DPSI). By optimizing the growth process we have produced X-ray and gamma ray detectors that show excellent charge transport properties, with a high hole mobility of 190

cm^2/Vs and a high hole mobility-lifetime (μτ) product of 2.7 x 10^{-3} cm^2/V, combined with a low dark current of 2.9 nA cm^{-2} operating at a field strength of 1000 V/cm. These $FAPbBr_3$ detectors show well-resolved low energy gamma peaks from 241Am, with an energy resolution of 25.6% FWHM at 59.5 keV.

Abstract

We investigate charge transport in both 4H–SiC semiinsulating bulk graphene/semiinSiC/Ni sensor and epitaxial graphene/epiSiC/subsSiC/Ni Schottky barrier diode structure. Using the laser-induced Transient Current Technique (L–TCT), combined with alpha spectroscopy and I–V characterization, we investigate charge transport across either the bulk or epilayer and adjacent substrate. Our results reveal rapid space charge formation at all structures, even under pulsed bias, attributed to electron depletion. It is shown that in contrast to metallic electrodes showing fast damped oscillations, the graphene electrodes lead to significantly slower non-oscillating exponential-like current waveforms. Observed phenomena were successfully described by theoretical model based on surface plasmons in both sensors. These findings highlight the importance of the transient current technique for the investigation of SiC sensors.

This research was supported by the DOE Laboratory Directed Research and Development Program through Lawrence Berkeley National Laboratory.

Abstract

Perovskite $CsPbBr_3$ is promising as next-generation room temperature semiconductor gamma-ray detector. While remarkable energy resolution has been achieved (e.g., 1% at 662 keV) for $CsPbBr_3$, its timing resolution is expected to be limited by the charge transport process as semiconductor (as a reference, timing resolution is several ns or worse for semiconductor CdZnTe or TlBr). Here, we report sub-nanosecond time resolution utilizing the prompt Cherenkov emission from the $CsPbBr_3$ as fast timing signal while maintaining its good energy resolution. We demonstrate successful simultaneous readout of semiconductor charge induction signal and SiPM Cherenkov light signal. By associating the Cherenkov light signal with the charge signal, good energy resolution of ~3% at 511 keV and sub-ns coincidence timing resolution of ~ 583 ps with ^{22}Na gamma-ray source were achieved simultaneously. We expect further improvement of time and energy resolution with a high-frequency SiPM read-out PCB and a dedicated charge-readout PCB with integrated high-performance pre-amplifiers. Built upon the high energy resolution and the ability to provide spatial information of gamma-ray interaction, the sub-ns fast timing capability would markedly broaden the applications of $CsPbBr_3$ gamma-ray detectors that are projected to have low cost compare to CdZnTe.

Abstract

Organic field-effect transistors are promising candidates for ionizing radiation dosimetry due to their low-cost fabrication, large-area processability, and tissue-equivalent composition. However, their response is strongly affected by environmental species, such as oxygen and moisture, which can induce charge traps and compromise detector stability. Here, we investigate the role of Parylene-C encapsulation in TMTES:PS-based OFET X-ray detectors. The encapsulation layer preserves the pristine electrical performance while significantly improving shelf stability. Under X-ray irradiation, uncoated devices exhibit air-dependent transient dynamics, with recovery in air and integrative behavior in vacuum. In contrast, Parylene-C-coated devices show stable and cumulative response independently of the surrounding environment, indicating that encapsulation suppresses air-induced trap formation. Trap density of states analysis supports this interpretation, revealing additional shallow trap states only in uncoated devices irradiated in air. Encapsulated OFETs further display a dose-dependent threshold-voltage shift, with a maximum sensitivity of 0.109 ± 0.002 V Gy^{-1} and long-lived retention of the absorbed dose information. These results demonstrate that Parylene-C encapsulation is not only an effective strategy to improve environmental stability, but also a key tool to control the radiation response of organic transistor-based dosimeters.

Li- and B-Doped $CsPbBr_3$ Composites for Fast Radiation Scintillation Detection (#2944)

Mohamed Boukhicha, Spencer A. Reisbick, Cultrera Luca, Tsang Thomas

Brookhaven National Laboratory, Instrumentation, Upton, USA

Abstract

Efficient and scalable scintillators are critical for applications in medical imaging, nuclear security, and environmental monitoring. Here, we investigate lithium-6 and boron-10 doped $CsPbBr_3$ perovskite-polymer composites for dual-mode neutron and X-ray detection. A scalable ball-milling process was used to incorporate neutron-sensitive isotopes into $CsPbBr_3$ nanocrystals embedded in PMMA and PDMS matrices. The resulting composites combine the neutron capture capabilities of lithium-6 and boron-10 with the favorable optical properties of $CsPbBr_3$, including high light yield, emission near 520 nm, and sub-nanosecond decay times. HR-TEM analysis confirmed a homogeneous distribution of ~10 nm nanocrystals throughout the polymer matrix. Synchrotron-based measurements further demonstrated strong radioluminescence and fast scintillation response under X-ray excitation. Preliminary studies also indicate promising neutron and alpha-particle scintillation performance, highlighting the potential of these flexible and scalable composites for next-generation radiation detection technologies.

Physics-Informed 3D Gaussian Splatting for Multi-View Compton Camera Imaging (#1292)

Rui Ma, Liang Li

Tsinghua University, Department of Engineering Physics, Beijing, China

This work was supported by National Key R&D Program of China (No. 2023YFA1608401).

Abstract

High-resolution 3D Compton imaging is essential for quantitative environmental monitoring. Traditional Maximum Likelihood Expectation Maximization (MLEM) suffers from voxel discretization penalties. Without ground-truth references, MLEM's required early stopping creates a dilemma between severe depth-elongation and late-stage noise deterioration. Meanwhile, modern deep learning models suppress noise but lack zero-shot generalization. To bridge this gap, we present a zero-shot, physics-informed 3D Gaussian Splatting (3DGS) framework. Although likelihood computation utilizes differentiable voxelization, the fundamentally continuous nature of 3DGS introduces implicit spatial regularization, bypassing rigid voxel constraints. It rigorously decouples the morphological probability density from overall source activity via an analytical optimal scaling mechanism. In simulations, 3DGS eliminates background artifacts, yielding up to 5.7 dB Peak Signal-to-Noise Ratio (PSNR) improvement over MLEM in 4-view phantom reconstructions. Validated experimentally on an H3D M400 detector within a 0.125 m³ workspace, 3DGS overcomes MLEM's depth-elongation and noise deterioration without arbitrary early stopping. It achieves an angular resolution of ~9° and excels in practical multi-isotope identification while strictly preserving relative activity linearity. This training-free paradigm offers a robust, quantitative tool for radiation monitoring.

Benchmark of the H3DD_UMv5 Waveform Sampling ASIC for Pixelated Room-Temperature Semiconductor Detectors (#1336)

Yuefeng Zhu, Gianluigi D. Geronimo, Zhong He

University of Michigan, Nuclear Engineering and Radiological Sciences, Ann Arbor, USA

This material is based upon work supported by the Defense Threat Reduction Agency under Contract # HDTRA1-24-C-0002. Any opinions, findings and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the Defense Threat Reduction Agency.

Abstract

H3DD_UM ASIC has been developed at the University of Michigan since 2017. This paper summarizes the performance of the most recent version H3DD_UMv5 ASIC. The electronic noise was measured to be 1.2 keV FWHM at 700-keV dynamic range with a 20×20×15 mm^3 CdZnTe detector attached but not biased. Such low noise enables an excellent energy resolution of 0.37% FWHM at 662 keV for single-pixel events. For all events, the measured energy resolution is 0.52 % FWHM. The low-energy threshold can be as low as 2.0 keV using the 200 keV dynamic range. The nonlinearity of the AISC is around 0.6% and it can be calibrated using the internal test pulse.

[1] Brookhaven National Laboratory, Upton, USA; [2] Stony Brook University, Stony Brook, USA; [3] Savannah River National Laboratory, Aiken, USA

Abstract

We report recent progress in the development of CdZnTe (CZT) and CdZnTeSe (CZTS) position-sensitive virtual Frisch-grid (VFG) gamma-ray detectors and detector arrays. The high 3D position sensitivity enabled by the VFG design allows correction of response non-uniformities caused by crystal defects. A key challenge in current large-volume CZT/CZTS detectors is the lateral displacement of charge carriers, which may exceed 1-2 mm over a >1 cm drift distance, strongly affecting the imaging capabilities of gamma cameras. These displacements are closely tied to crystal defects, such as dislocations and sub-grain boundaries, which are always present even in the highest-quality crystals. To address this issue, we propose using detectors with smaller-than-typical cross-sectional

areas (4×4 or 5×5 mm²), which match the size of the basic element in a coded-aperture imaging system. Improving position and energy resolution through the application of neural network algorithms is critical for the development of high-performance and reliable detector systems. We demonstrate that the neural network approach yields better results and requires significantly less calibration data because it handles the continuous distribution of events within the detector, whereas the conventional correction-matrix approach relies on discretized values resulting from detector segmentation. We present the results of testing these devices and discuss their advantages and shortcomings.

Measurement of the energy response function of a photon counting prototype detector using the HEX-27 beamline at the Brookhaven National Laboratory; A method to derive an empirical model of the detector non-ideal behavior and to improve material discrimination by spectrum deconvolution. (#2142)

Abstract

Spectrum unfolding, or deconvolution, is a critical preprocessing step in X-ray image formation, particularly for spectral photon-counting detectors (PCDs). While an ideal detector records the full energy of an incident photon at a single pixel, realistic semiconductor detectors are governed by complex physical phenomena. Charge sharing, K-fluorescence escape, and pulse pile-up are the dominant factors that distort the recorded energy of the recorded signal. Thes first two effects are significantly exacerbated as pixel sizes decrease, leading to spectral degradation that compromises material discrimination and CNR, challenging the multi-energy imaging system.

This study presents a comprehensive characterization of the energy response function (ERF) for a PCD module developed by AMS-OSRAM, utilizing a CdZnTe (CZT) crystal with a native pixel pitch of 341 µm × 365 µm coupled to three ultra-low noise ASICs. The work was conducted at the HEX-27 (High Energy X-ray Scattering) beamline at Brookhaven National Laboratory. The detector was exposed to monochromatic X-ray beams from 30 keV to 140 keV at a flux of 9 Mcps/mm². The complete spectral response was mapped at high resolution, by sweeping the detector's five energy thresholds. The measurements enabled the derivation of an empirical model describing the ERF of the AS5920M/CZT module, accurately capturing inherent spectral features and tailing effects. To verify this empirical model, the derived response was convoluted with ideal spectra generated via SpekCalc. The resulting reconstructed distorted spectra matched well the measured detector output.

Finally, we propose a correction methodology applied to individual energy bins. By compensating for spectral

distortions, enhanced contrast-to-noise ratio (CNR) can be achieved, thereby significantly improving the accuracy of material separation.

Abstract

Future hybrid pixel detectors for particle tracking and imaging require dense, low-inductance interconnections that can distribute clean power, sustain multi-gigabit data transmission, and minimize non-sensitive area. Conventional wire-bonding constrains input and output access to the die periphery, and results in long internal power routing as well as dead area which prevents close tiling of chips. This contribution presents a three-dimensional integration approach for the readout of hybrid pixel detectors based on Through-Silicon Vias (TSVs) fabricated after complementary metal-oxide-semiconductor processing. Timepix4 readout chips are used as a test vehicle. Vias are etched from the back side of thinned chips, insulated from the substrate, metallized, and connected to a back-side redistribution layer that routes power and signals to an array of bonding pads on which solder balls can be deposited. The resulting interconnects replace wire bonds and allow the chip to be soldered directly to a carrier printed circuit board. Several processed Timepix4 batches have been evaluated. A custom-designed test system allows measurement of interconnect quality for signal transmission and power delivery. TSV-processed chips have also been co-integrated together with silicon-photonics into module demonstrators. The tests demonstrate successful operation of Timepix4 after TSV processing, including 5 Gbit/s data transmission and stable power delivery through the back-side interconnect stack. The presentation will discuss the processing flow, test system

design choices, assembly and test results, and the suitability of solder ball-grid arrays and anisotropic conductive paste for permanent chip-to-board attachment.

Abstract

Gallium arsenide (GaAs) has broad application prospects as a material for photon counting detectors (PCDs). In this study, we investigate carrier dynamics and polarization in Cr-compensated GaAs (GaAs:Cr) via infrared transient current analysis and clinical X-ray temporal response experiments. The transient current results indicate that while massive carrier generation under high-intensity illumination can induce localized polarization, the deep energy levels introduced by Cr doping effectively preserve dynamic charge neutrality. By capturing and recombining excess carriers, this Cr-compensation successfully mitigates polarization effects, significantly improving detector signal stability up to an ultra-high clinical flux of 2.7 Gcps/mm^2.

Abstract

Advances in the fabrication of detector-grade GaAs semiconductors through chromium compensation have enabled the development of imaging sensors with high detection efficiency, energy resolution, high-flux tolerance, and enhanced radiation hardness, providing improved performance in the mid-energy X-ray range compared to conventional Si and Cd(Zn)Te sensors. Detection efficiency in semiconductor sensors strongly depends on sensor thickness, as the active detection volume scales directly with it. High absorption efficiency up to 80 keV is required in medical computed tomography (CT) and security imaging, which can be achieved using 2 mm thick GaAs sensors.

GaAs sensors with thicknesses from 0.3 mm to 2 mm manufactured by Advafab were developed, characterized, and evaluated with different photon-counting readout electronics. High-resistivity GaAs wafers were processed using Cr compensation, followed by lithography, metallization, dicing, and flip-chip bonding to various readout ASICs. The sensors were evaluated under X-ray irradiation to investigate detection efficiency, count-rate uniformity, charge transport, stability, and imaging performance. The 2 mm thick sensors demonstrated excellent image uniformity and operation at extreme X-ray fluxes up to 1100 Mcnt/s/mm2 with stability better than 2% over 30 s. Sidewall etching of diced GaAs improved sensor performance by reducing leakage current and enhancing electric field uniformity. The results highlight GaAs:Cr as an effective material for photon-counting X-ray imaging in medical, synchrotron, and industrial applications.

The Timepix ASIC Family: Past, Present, and Future (#3005)

Rafael Ballabriga, Xavier Llopart Cudie, Michael Campbell, On behalf of the Medipix2, Medipix3 and Medipix4 Collaborations

CERN, Meyrin, Switzerland

Abstract

This summary reviews the evolution of the Timepix family of hybrid pixel detector readout ASICs, from Timepix in 2006 through to the recently released Timepix4 and the forthcoming Picopix demonstrator. The early versions had a regular matrix of 256x256 pixels. Each generation introduced an architectural innovation: per-pixel programmable Time-of-Arrival (ToA) or Time-over-Threshold (ToT) mode selection (Timepix, 250 nm MOS, 2006, Medipix2 Collaboration); data-driven triggerless readout with simultaneous time and energy measurement (ToA/ToT) and a 1.56 ns on-pixel TDC (Timepix3,130 nm CMOS, 2013, Medipix3 Collaboration); simultaneous ToA/ToT with logarithmic gain mode, improved energy resolution, and dead-time-free continuous read/write (Timepix2,130 nm CMOS, 2018, Medipix2 Collaboration); and 195 ps ToA binning over a four-side buttable 448x512 matrix using through-silicon via (TSV) technology (Timepix4, 65 nm CMOS, 2019, Medipix4 Collaboration). The forthcoming Picopix (28 nm CMOS, submission foreseen in 2026) targets ~35 ps ToA binning with on-pixel clustering, on-chip time calibration, and packet sorting. Key quantitative parameters—timing resolution, hit rate, active area, power consumption, and readout bandwidth—are compared across all five generations. Representative applications and the knowledge-transfer impact of the Medipix Collaborations model are discussed.

This work was supported by the INFN-CSN5 experiment TIMEPIX4.

Abstract

Timepix4 is the latest generation of the readout ASIC developed by the Medipix4 Collaboration for hybrid pixel detector technology, featuring a 448 x 512 matrix with a 55 µm pitch. Operating in data-driven mode, it provides simultaneous Time of Arrival (ToA) and Time over Threshold (ToT) information for each hit. This allows for multi-pixel signal clustering to mitigate charge sharing and fluorescence escape, while calibrated ToT values provide per-pixel energy measurement. Such capabilities enable high-resolution X-ray spectral imaging, providing accurate energy deposition information for each detected event and greater post-processing flexibility compared to traditional threshold-based photon-counting systems. In this work, we present the first full-spectral micro-CT images acquired with a Timepix4-based detector operating in data-driven mode. The detector is equipped with a 1 mm-thick CdTe sensor, making it suitable for X-ray energies commonly used in biomedical applications. Tomographic scans were performed at the INFN PEPI laboratory using a microfocus X-ray tube (80 kV, 20 µA). The study evaluated a custom plastic phantom containing three distinct contrast agents: silver, iodine, and gadolinium. Projections were acquired over 360° with a reconstructed voxel size of 33 µm. The resulting 3D attenuation spectra were processed using a basis material decomposition algorithm, producing independent 3D density maps for each contrast agent. The results confirm the feasibility of full-spectral micro-CT imaging using the Timepix4 ASIC, demonstrating its ability to capture 3D attenuation spectra at high spatial resolution. While data rate management remains a challenge, the ability to resolve full attenuation spectra in 3D enables precise multi-material identification in a single scan. This capability offers significant potential for advanced applications in biomedical research and materials science.

Abstract

X-ray imaging systems are widely used in industries such as homeland security, non-destructive testing, archaeological research, and medicine, where accurate material identification is often essential. Examples include explosives screening in airport luggage, product quality testing on a production line, and content characterization in historical manuscripts. Photon-counting detectors provide high spatial and energy resolution, along with full spectroscopic information on a per-event basis, and are therefore well suited for machine learning (ML) approaches to material identification. One example of such a detector is the Timepix3, which records single events at fluxes up to 40 Mhits/cm^2/s. Previous work, presented at this conference, demonstrated the feasibility of training an ML classifier (Gradient-Boosted Trees) on measured X-ray spectra acquired with a 12x1 Timepix3 (bump-bonded to 1 mm CdTe) detector and reported initial identification results on a multi-material phantom. This contribution extends that work, addressing two limitations of its results: the restricted size of the experimental material database and the lack of quantitative model diagnostics. The database is supplemented with simulated spectra (generated with the Allpix Squared framework) for materials that are difficult to obtain as pure reference samples, and the consistency between simulated and measured data is assessed. The extended database is then used to retrain the classifier, and standard ML diagnostics are reported to characterize model behavior. The performance of this approach will be compared to classical techniques such as base-material decomposition.

Full Scale Microstructural Imaging Based on Energy dispersive X-ray Diffraction using Timepix3/4 with CdTe Sensor (#2737)

Jan Jakubek[1], Roman Nebel[1], Jiri Volny[1], Daniel Vavrik[2]

[1] ADVACAM s.r.o., Prague, Czech Republic; [2] Institute of Theoretical and Applied Mechanics, Czech Academy of Sciences, Prague, Czech Republic

Abstract

This contribution extends the technique of the fast energy dispersive X-ray diffraction (XRD) in transmission mode for inspection of macroscopic objects, as described in our previous work [1], published recently by Nature Scientific Reports. This technique utilizes the event-based registration of diffracted X-ray photons with simultaneous timing

and energy information as provided by Timepix3/4 detectors. It enables rapid diffraction measurements with a polychromatic X-ray source, eliminating the need for mechanical angular scanning while preserving spatially resolved structural information.
Current XRD systems utilize relatively low-energy monochromatic X-ray beam (5-20 keV) which can only penetrate shallow layer close to the sample surface. Therefore, thick or dense parts cannot be analyzed through their entire volume using standard approaches. An alternative is the use of synchrotron sources, however, these are generally impractical for industrial applications.
A hard polychromatic X-ray source (X-ray tube) in combination with spectrally sensitive imaging detector such as Timepix3 or Timepix4 equipped with high-Z sensor (CdTe or CZT) overcomes above listed limits. This work focuses on optimizing detector performance by suppressing unwanted effects such as internal X-ray fluorescence and charge-sharing. Both of these effects degrade energy resolution, which directly impacts the quality of recorded XRD data. It will be demonstrated that an optimized detector, together with an event-sorting algorithm, can provide high-quality XRD data within a fraction of a second. Such speed enables 2D scanning across the entire volume of the inspected sample.

Abstract
Grating-based phase-contrast imaging (gbPCI) is a powerful tool for non-destructive testing and material analysis. In conventional X-ray imaging, only the attenuation of the X-rays is measured, resulting in low contrast between structures with similar absorption characteristics. With gbPCI, it is possible to not only get information about the absorption, but also the phase-shift of X-rays when propagating through material. For non-destructive testing and material analysis, the dark-field image provides complementary information, since it is sensitive to structures below the resolution limit of the system, which is primarily given by the pixel sizes of the detector. The pixel pitch is typically 50 µm or higher. With the dark-field image, it is possible to see porous or fibrous structures and estimate their sizes. A photon-counting and energy-resolving Timepix4 detector is used in this work. By setting energy cuts,

the sensitivity range can be maximized, allowing a more detailed structural analysis. Additionally, the quality of the imaging system can be improved by cutting unwanted energies. First test measurements with Timepix4 have shown the feasibility of phase-contrast imaging with this detector, by acquiring energy-resolved dark-field images of lycopodium spores and a piece of wood.

Abstract

Direct image reconstruction methods for Compton imaging such as Simple Back Projection (SBP) are widely used for their simplicity and robustness. Difficulties arise when imaging low-activity, non-point sources that span a significant portion of the detector's field of view (FOV). The detector's directional photopeak efficiency will heavily skew the collected data, and may result in a biased image that does not accurately visualize the extent and intensity of the whole object. This work proposes a SBP imaging algorithm with rotational corrections that smooth out the directional efficiency of the CdZnTe detector and generate a 4π FOV Compton image that accurately visualizes the distribution of an extended radioactive source. Experimental results demonstrate the ability to differentiate between naturally occurring radioactive material (NORM) such as Ra-226 and Th-232 found in the concrete masonry unit (CMU) walls and the lack of NORMs from the windows. This was achieved by placing the detector 6" away from a CMU wall and a floor-to-wall window of roughly the same size and rotating it continuously as it collected data. The resulting Compton image clearly showed regions of high and low intensity corresponding to the locations of the CMU wall and window, successfully mitigating the effects of directional efficiency. Further work will investigate source-to-detector distance dependence and field applications, with the goal of applying similar methods to environmental monitoring and surveying scenarios to visualize areas of elevated radiation levels and contamination.

High-Energy Gamma Transmission Imaging with a 3D-CZT Detector Using Ring Localization (#1362)

Peter G. Hotvedt, Yuefeng Zhu, Matthew Granados, Zhong He

University of Michigan, Nuclear Engineering and Radiological Sciences, Ann Arbor, USA

This material is based upon work supported by the Defense Threat Reduction Agency (DTRA) under Contract No. HDTRA124C0002. Any opinions, findings and conclusions, or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of DTRA.

Abstract

Transmission imaging requires a backing photon-sensing detector to accurately measure the interaction site and energy of each incident photon in future systems for material identification. 3D-CdZnTe detectors currently approximate the centroid of each electron cloud as the gamma interaction site with subpixel position sensing, but at high photon energies this measure may be biased by several millimeters from the true gamma interaction position, creating a noisy image. The ring localization technique constructs a ring of potential locations of the interaction site. The ring has its center at the measured centroid and has a radius equal to the average displacement between the interaction site and the centroid. Overlapping multiple rings on a per-event basis recovers this positional error. To demonstrate this recovery, a Th-228 source was placed behind a tungsten collimator with a 0.5-mm gap, which was aligned across a row of pixel electrodes to create centroid and ring images. Images were made using suspected Compton scattering events with a total event energy > 2 MeV. Two specific pixels were investigated in both images: one in the exposed region and one in the shielded region. The ring localization image shows an improved signal-to-noise ratio in both the exposed and shielded pixels compared to the centroid image. The pixels in the ring image also demonstrate a statistically significant difference between the average signal in the exposed and shielded regions. Subdividing the pixels reveals a count gradient on the investigated pixel, with the higher average signal in line with the collimator region. Future work will add more event types to get a better measure of the image resolution.

Abstract

Three-dimensional position-sensitive Cadmium-Zinc-Telluride (3D-CZT) detectors are promising in astrophysics. However, the specific space environment and scientific observation requirements impose numerous challenges on the readout electronics, including achieving low noise, high timing precision, and high count rates, while balancing high integration with low power consumption. Thus, we propose MPT3128, a 128-channel mixed-signal application-specific integrated circuit (ASIC) for 3D-CZT detectors. Each channel integrates a low-noise charge-sensitive amplifier (CSA), fast and slow shapers, a 12-bit ADC (shared between two channels), and a time-to-digital converter (TDC) with a resolution of 312.5 ps. Specifically, for cathode timing, it features an adjustable fast-shaper peaking time and a triple-threshold timing scheme. Experimental results demonstrate that the analog front-end achieves low timing jitter (~2 ns even at 4.5 fC charge input), low electronic noise (202 e^- rms), and high energy resolution (5.7 keV FWHM at 511 keV), while featuring fully digital output and control interfaces, facilitating system integration. Furthermore, with all channels active, the triggering rate reaches 55 kHz per channel. The unit has a relatively low power consumption (6.34 mW/channel), making it a promising solution for advanced radiation applications.

Abstract

The growing role of solution-processable materials in novel, sensible radiation detectors has established materials like organic semiconductors and perovskites as promising alternatives to traditional ones. Solution-processable materials posses the unique characteristic to be semiconductors that can be processed in liquid form, and thus are extremely useful to develop thin, large-area and inexpensive devices. Quantum Dots have only recently started to draw attention as candidates for innovative, tunable detectors. These nanoparticles possess wide tunability possibilities, facile synthesis, ambient stability and are constituted often of High-Z elements such as Pb, Cd, Se etc. QDs' optoelectronic properties are strongly dependent on their size, which is tunable during synthesis. Within a size range for every QD material, it is then possible to select the best ones for each application. Recent results suggest that QD-based detectors have high X-ray sensitivity even with low-power operation, are radiation hard and retain their stability under ambient condition. However, a still unexplored and exciting question is if the best materials for direct radiation detection could still perform efficiently in QD form. A positive answer would mean a new, unprecedented way to fabricate such detectors, exploiting the advantages of solution-processable materials such as low-cost, large-area deposition, casting on flexible substrates etc. With this question in mind, and inspired by the excellent detection characteristics of CdZnTe detectors, in this work we synthesized CZT QD and employed them in drop-cast photodetectors. We assessed their X-ray detection capabilities in the 5-50 keV range with low-power biasing, observing a ready, repeatable response to the radiation. This result, albeit still early, seems to suggest a positive answer to our question, paving the way for the use of already established materials (CZT) in QD form for the development of new, advanced direct detectors.

High-Flux Performance of a Photon-Counting Detector for Spectral CT Based on the ColorCT ASIC (#1491)

Andrea Brambilla, Arnaud Peizerat, Kim Abdoul-Carime, Adrien Poizat, Jonathan Jonsson, Daniel Tran, Loick Verger

Univ. Grenoble Alpes, CEA-Leti, DOPT, Grenoble, France

CEA-Leti is a member of the Carnot institute network. This work was supported by the French ANR via Carnot institute funding.

Abstract

ColorCT is a novel readout ASIC for energy-resolved photon-counting detectors (ER-PCDs) dedicated to spectral X-ray computed tomography (CT). It is designed to sustain very high photon fluxes while preserving spectral performance under strict power consumption constraints. The ColorCT test chip features an 11 × 11 pixel matrix (330 µm pitch) and 8 energy bins. A fast analog front-end delivers short pulses (13 ns peaking time, 24 ns FWHM), enabling high count rate capability. A Digital Reset circuit mitigates pile-up and prevents detector paralysis, ensuring a monotonic increasing behavior of the count rate with the X-ray flux with a saturation value of 30 Mcps. A digital charge sharing correction (CSC) improves the spectral accuracy. The ASIC was coupled to a CdTe crystal to perform X-ray characterizations. Experimental results demonstrate improved count rate and spectral response obtained with the Digital Reset and the CSC, with a power consumption of 3 mW/mm² at 3 10^7 cps/px (3 10^8 cps/mm²).

Abstract

CZT Compton cameras have demonstrated great promise for nuclear medicine. We are designing a dual layer CZT Compton camera to enhance angular resolution with respect to current single-layer cameras. An application specific integrated circuit (ASIC) that provide excellent 3D position, energy resolution and high data throughout is required for this. A multi-channel ASIC is presented in this work to overcome these challenges. It is composed of 16 anode readout channels, plus a cathode channel, that each contain a charge sensitive amplifier (CSA), pulse shaper, programmable gain amplifier (PGA), peak detector, and configurable peak detector reset dissipating 12 mW per channel to support low-noise and high dynamic range. The channels are designed for a target energy of 218keV & 440keV used in ^{225} Ac Compton imaging, with a worst-case 0.81% non-linearity over the dynamic range of 30 keV to 2.2 MeV. Each channel can handle up to 2 nA of leakage current without performance degradation and yields 1.33% FWHM at 662 keV with a single-pixel capacitance of 29.1 pF for each (1.225 mm)x(1.225 mm) pixel. The rise time of each CSA is 150 ns while the shaper peaking time is 320 ns to enable fast readout with a configurable gain of 7, 13, 45, 81, and 132 mV/fC from the PGA. This work demonstrates a compact, scalable readout platform for CZT-based Compton imagers and other room-temperature semiconductor detector systems requiring high energy resolution.

Performance evaluation of CZTS grown with higher purity CdSe starting material (#2698)

Utpal N. Roy, Joshua Kleppinger, Ralph B. James

Savannah River National Laboratory, ELM, Aiken, USA

Abstract

CdZnTe (CZT) has been the most commercially successful semiconductor material for room-temperature X-ray and gamma-ray radiation detector applications. It is considered as the gold standard for detector applications that

require spectral and often spatial information in a compact instrument. However, CZT still contains a high density of performance-limiting defects such as high concentrations of sub-grain boundary networks, Te inclusions and compositional inhomogeneity in as-grown ingots. Adding a small amount of selenium (Se) in the CZT matrix was found to successfully mitigate the performance-limiting defects and provide for better compositional homogeneity. Thus, the new quaternary $Cd_xZn_{1-x}Te_ySe_{1-y}$ (CZTS) is emerging as a next-generation compound semiconductor, potentially surpassing the material quality of CZT. However, the purity of CZTS material is not on par with commercial CZT, principally due to the lack of availability of commercial high-purity CdSe. The presence of the impurities in CZTS caused by the lower-purity CdSe starting material was found to impose a detrimental effect on the charge transport properties of CZTS, resulting in adverse effects on the charge collection and detector performance. Here, we report for the first time on the growth and characterization of $Cd_{0.9}Zn_{0.1}Te_{0.98}Se_{0.02}$ grown by vertical Bridgman and by the traveling heater method (THM) using higher-purity CdSe starting material.

Merit-Function-Guided Porosity Control in Directional Solidification of CZT (#2985)

Aimen E. Gheribi[1], Khedija Younsi[1], Nikolay Chorbadzhiev[1], Elhadi Hammoutene[1], Frederic Belanger[1]

[1] 5Nplus, R&D, Montreal, Canada; [2] 5Nplus, R&D, Montreal, Canada

Abstract

Directional solidification (DSM) enables rapid growth of cadmium zinc telluride (CZT) ingots with superior scalability and geometric flexibility compared to the travelling heater method (THM). However, the strongly non-equilibrium conditions inherent to DSM promote gas bubble nucleation, growth, transport, and coalescence, leading to porosity that degrades detector performance. Bubble-induced defects distort internal electric fields, enhance charge trapping, reduce the carrier mobility–lifetime product ($\mu\tau$), and increase leakage current and electronic noise through impurity segregation and secondary phase formation. In contrast, THM operates closer to thermodynamic equilibrium and therefore minimizes such defects, albeit at reduced growth rate and scalability.

DSM-grown CZT typically exhibits axial heterogeneity, with increasing bubble density and size toward the last-to-solidify region. This results from coupled interactions between volatile-species thermodynamics, buoyancy-driven transport, capillarity, coalescence, and solidification kinetics. Bubble coalescence and accumulation in the upper melt region significantly amplify porosity near the end of solidification, producing larger pores that are more easily entrapped and more detrimental to detector uniformity.

To describe these mechanisms, a physics-based dimensionless framework is introduced using transport, thermodynamic, and interfacial scaling parameters, including an escape number comparing bubble migration and interface growth velocities, as well as Bond and Capillary numbers governing deformation and stability. Within an atomistic-informed thermophysical model at 5N Plus, temperature- and composition-dependent properties are used to evaluate these parameters and define a predictive merit function for DSM optimization. This framework identifies

conditions that promote bubble escape, suppress coalescence and entrapment, and reduce porosity while preserving the advantages of rapid CZT crystal growth.

Energy-Resolved Effective Focal-Spot Characterization of a CdTe-Timepix3 Nanofocus XCT System Using Orthogonal Slanted-Edge Measurements (#1354)

Gerardo A. Roque, Michael K. Schütz, Juan S. Useche, Simon Procz, Michael Fiederle

Albert-Ludwigs-Universität Freiburg, FMF, Freiburg, Germany

Abstract

Spatial resolution in high-magnification X-ray imaging is limited by the detector's pixel aperture and the X-ray source focal spot size. The latter caps the achievable geometric magnification, and depends on photon energy, observation direction, and sample X-ray attenuation. This work presents an energy-resolved characterization of the effective focal spot size of the Freiburg Materials Research Center nanofocus X-ray imaging system, that combines the Hamamatsu L10711-03 Tungsten-anode nanofocus X-ray tube with a 12 × 1 Timepix3 spectroscopic photon-counting detector (PCD) array equipped with 1 mm thick Cadmium Telluride (CdTe) sensors. A single high-absorbing Steel slanted edge is used to implement the double-distance edge-response method, applied in horizontal and vertical orientations to measure the focal spot size in both principal directions. For energy bins from 15 keV to 50 keV, an in-contact edge image captures detector-generated blur, while a magnified edge image embeds both detector blur and source penumbra. After energy calibration, flat-field correction, and event declustering, edge-spread functions are oversampled, differentiated to obtain line-spread functions (LSF), and Fourier-transformed to obtain energy-resolved Optical Transfer Functions, OTF(E). The per-bin ratio of the mixed and contact OTF removes the detector contribution to image blur and yields a source-plane OTF and LSF, from which the effective focal spot size is extracted. Preliminary analysis suggests measurable variation in the recovered source-plane profiles across energy windows and between horizontal and vertical orientations, indicating that the effective focal spot cannot be treated as energy-independent. The study relies on a practical method for source characterization in spectroscopic photon-counting X-ray systems, to achieve a thorough resolution characterization of the nanofocus imaging system.

Digital Signal Processing of Large-Volume, Pixelated $CsPbBr_3$ for Gamma-ray Spectroscopy (#1601)

Michael Streicher[1], Matthew Petryk[1], Josh Palmer[2], Indra Pandey[2], Sara Abraham[1], Ryan Parsons[1]

[1] H3D, Inc., Ann Arbor, USA; [2] Actinia, Inc., Evanston, USA

This material is based upon work supported by the Defense Threat Reduction Agency under Contract No. HDTRA225CE001. Any opinions, findings and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the Defense Threat Reduction Agency.

Abstract

Over the course of the past decade, $CsPbBr_3$ has emerged as perhaps the most promising alterative room temperature semiconductor material for gamma-ray spectroscopy. $CsPbBr_3$ has been shown to be grown quickly, and relatively inexpensively, while being surprisingly defect tolerant. Fifteen 1-cm-thick $CsPbBr_3$ samples, attached to printed circuit boards with a low-temperature melting alloy, were evaluated over the course of this project. A custom evaluation system containing COTS preamplifiers and oscilloscopes was used to correct these samples for depth-of-interaction effects. While yields were initially fairly poor, the best sample achieved better than 1.5% FWHM energy resolution at 662 keV for the entire 0.25 cm^3 volume. Eight of the nine pixels in the device achieved energy resolution better and 1.5% FWHM at 662 keV. The device exhibited predicable conditioning effects. The device has been operating for several months, albeit not at continuous bias. The failing samples tended to have attachment issues; either the attachment failed and the $CsPbBr_3$ disconnected from the carrier board or all pixels exhibited poor performance and instability which could also be due to issues with the device attachment to the substrate. At the time of the conference, the authors expect to have preliminary results of a $CsPbBr_3$ gamma-ray spectrometer with volume greater than 1 cm^3 read out with pulse-waveform sampling preamplifiers integrated into an Application Specific Integrated Circuit (ASIC).

This work was supported by the Italian Ministry for University and Research (MUR), under PRIN2022 PNRR (P2022SE49Y, 2022ZEF2RE) projects, and the UKRI STFC Centre for Instrumentation SMART Managed Programme 24 - 26.

Abstract

In this work, we present a CdZnTe/CMOS spectroscopic linear-array detection system enabled by a wedge-bondable High Density Interconnect (HDI) interposer that allows bump-bonding on the detector side and wedge-bonding toward the readout electronics, significantly simplifying the interconnection constraints between the two elements [1],[2],[3]. The interposer layout is optimized to suppress inter-channel parasitics, yielding measured pixel-to-pixel and pixel-to-guard capacitances of 10.2 fF and 25.7 fF, respectively. Two custom 8-pixel CdZnTe detectors (500 µm pitch, 25 µm gap with 1 mm and 2 mm thickness respectively) were integrated with an 8-channel ultra-low-noise SIRIO charge-sensitive amplifier [4],[5] and characterized at room temperature. After integration, spectroscopic characterization was performed with 55Fe, 241Am, and 57Co radioactive calibration sources, demonstrating the capability of the system to cover a wide energy range (5–150 keV). Using a 50 ns peaking time on an external digital pulse processor, an average FWHM of 744 eV (Detector 1) and 850 eV (Detector 2) was measured on the pulser line, recording an optimum energy resolution of 1.4% at 122 keV, and paving the way for additional studies on larger detector arrays in high-flux spectroscopy applications.

Stabilizing the Detector Response of $CsPbBr_3$ Gamma-Ray Detectors

(#2010)

Matthew Petryk[1], Michael Streicher[1], Ryan Parsons[1], Sara Abraham[1], Josh Palmer[2], Indra Pandey[2]

[1] H3D, Inc., Ann Arbor, USA; [2] Actinia Detectors, Inc., Evanston, USA

This material is based upon work supported by the Defense Threat Reduction Agency under Contract No. HDTRA225CE001. Any opinions, findings and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the Defense Threat Reduction Agency.

Abstract

With greater photopeak efficiency and lower temperature growth processes, $CsPbBr_3$ is a promising alternative to CdZnTe (CZT) for room temperature semiconductor-based gamma-ray detectors. H3D, Inc. has characterized the stability of both single-pixel and pixelated 10mm thick $CsPbBr_3$ gamma-ray detectors. The best pixelated devices show a pattern of conditioning, whereby the device response stabilizes after 60 hours of bias. The best resolution obtained is 1% at 662 keV on a by-pixel basis, and 1.5% overall. The most stable detectors show clear photopeaks from ^{137}Cs during over 1200 hours of continuous operation. Though the stability is improved by contact engineering, surface polishing, and encapsulation, there is still significant drift in the peak over time. This drift causes the resolution to deteriorate over time and invalidates earlier calibrations. H3D has developed an algorithm to stabilize the response of these $CsPbBr_3$ detectors further by utilizing the known relationships between photopeaks and escape peaks. The algorithm operates on a per-measurement basis, requiring no knowledge of what isotope is being measured nor the past history of the device. This enables it to be applied in the field to arbitrary measurements, without requiring a convenient check source for pre-measurement calibration.

This material is based upon work supported by the Defense Threat Reduction Agency under Contract No. HDTRA225CE001. Any opinions, findings and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the Defense Threat Reduction Agency.

Neutron Irradiation Effects in β-Ga_2O_3 Radiation Detector Materials Investigated by Raman and Positron Annihilation Spectroscopy (#2161)

Shams Noor, Ming Liu, Austin Wells, Ge Yang

NCSU, Nuclear Engineering, Raleigh, USA

This work was supported by the U.S. Department of Energy (DOE) Office of Nuclear Energy under its Nuclear Energy University Program (NEUP) (Award No: DE-NE0009192) and under DOE Idaho Operations Office Contract DE-AC07- 051D14517 as part of a Nuclear Science User Facilities experiment (Award No: 21-24020). The authors also thank Colby Fleming for her assistance in irradiation experiments.

Abstract

Gallium oxide (Ga_2O_3) is an emerging material for next-generation nuclear sensors due to its ultra-wide bandgap, high thermal stability, and large critical breakdown field. However, its radiation tolerance and defect evolution mechanisms in reactor environments remain insufficiently understood, limiting predictive assessment of long-term device reliability and performance. In this work, we systematically investigate the effects of neutron irradiation with simultaneous thermal annealing on β-Ga_2O_3 using positron annihilation lifetime spectroscopy (PALS), Raman spectroscopy, and polarized optical microscopy to probe irradiation-induced changes across atomic, defect, and microstructural length scales, providing complementary insight into defect formation, evolution, and recovery mechanisms under neutron exposure.

Monoclinic β-Ga_2O_3 samples were irradiated in the North Carolina State University PULSTAR reactor at room temperature (RT) and 700 °C. Microstructural characterization and PALS confirmed vacancy-type defects in the RT irradiated samples, while their absence at high temperature suggests thermally activated point defect suppression through increased atomic mobility. Raman spectroscopy revealed irradiation-induced microtilting in both cases, whereas the absence of Raman modes associated with gallium-clusters and oxygen-vacancy indicates overall defect concentrations remained low though detectable by the highly sensitive PALS technique. Together, these results show β-Ga_2O_3 is a promising material for nuclear sensing while unveiling key insights into its behavior under irradiation.

ROIC/ASICs for Radiation Detection and Imaging (#3349)

Dirk Meier

Integrated Detector Electronics AS - IDEAS, Oslo, Norway

Abstract
IDEAS has a long heritage in designing detector readout integrated circuits (ROICs) and electronic systems for scientific applications. You can use our VATA and IDE-type chips for reading out your high-channel-count detectors, e.g., strips or pixels on silicon, CZT, or scintillators with PMTs or SiPMs. For space applications, and with flight heritage, our radiation-hardened ASICs enable compact, low-power detectors. Building on this foundation, IDEAS is contributing to next-generation instruments and missions: Space radiation monitors deliver real-time dosimetry and particle spectra (NORM, and Galileo RMU). CZT-based systems (SRE4001, GDS-100) deliver high-resolution gamma spectroscopy and x-ray imaging in a modular form. Our new designs of ADC- and infrared controller ASICs (NIRCA) help minimizing infrared imaging systems and cameras. In my presentation I will focus on the ASICs and ROICs that we can supply and our new developments.

TS-02-02

Toward Information-Efficient Photon Detection: CMOS SiPMs and Multi-Threshold Readout ASICs (#3352)

Hui Lao, Guanning Su

RAYQUANT Technology Co., Ltd., Ezhou, China

Abstract
Detecting photons is only the beginning. How can we preserve and make better use of the information they carry? At Rayquant, we develop both CMOS silicon photomultipliers (SiPMs) and multi-voltage-threshold (MVT) readout ASICs, linking photon detection with timing readout. This presentation highlights our latest SiPM devices, measured photon detection and timing performance, and timing results from our MVT ASIC and SiPM–MVT experiments. We will also share applications of our SiPMs in PET imaging and radiation detection.
Beyond existing products, we will explore how detector-specific requirements can shape new SiPM and readout ASIC development, turning real detection challenges into working silicon.

TS-02-03

From Semiconductor Sensors to Hybrid Pixel Detectors: Advafab's Fabrication and Integration Capabilities (#3301)

Ben Panesar, **Juha Kalliopuska**, Sami Vahanen

ADVAFAB, Helsinki, Finland

Abstract
Advanced radiation imaging requires sensor materials, electrode structures and interconnection processes tailored to the application and readout electronics. This presentation introduces Advafab's sensor fabrication and hybrid integration capabilities, with a focus on silicon and compound semiconductor sensors, including GaAs and Cd(Zn)Te, for scientific, medical and industrial imaging.
We present the manufacturing route from sensor design and electrode processing to under-bump metallisation, wafer-level solder bumping, precision dicing and flip-chip bonding to readout ASICs. Particular attention is given to material-dependent processing requirements, compatibility between sensor contacts and interconnects, and electrical characterisation supporting detector quality.
The presentation also outlines Advafab's development of compound semiconductor foundry capabilities and opportunities for customer-specific sensor fabrication and process development. Attendees will gain a practical overview of how Advafab supports detector development from initial prototypes towards repeatable production, connecting sensor manufacturing with the requirements of complete hybrid pixel detector assemblies.

Real-Time Pile-Up Recovery and High-Resolution Signal Processing for SDDs using PurSamurAI (#3305)

Yoshihiro Endou[1], Masaki Takamaru[2], Kazuki Otomo[2]

[1] TechnoAP Co.,Ltd., Research and Development Department, Hitachinaka-City, Japan; [2] TechnoAP Co.,Ltd., Sales Department, Hitachinaka-City, Japan

N/A

Abstract
In spectroscopy using Silicon Drift Detectors (SDDs), signal pile-up in high count rate environments remains a primary challenge, significantly degrading energy resolution and throughput. This presentation introduces "PurSamurAI" (Pile-up Recovery via Smart Algorithm for Multi-pulse Unmixing and Reconstruction AI), a novel algorithm designed to overcome this limitation. By implementing a pre-trained inference model specialized for

waveform unmixing, PurSamurAI separates and recovers overlapping pulses in real time—events that are conventionally discarded. This approach minimizes spectral degradation even at extremely high input count rates, successfully achieving both high throughput and high energy resolution simultaneously. Furthermore, the architecture provides the flexibility for users to optimize the inference model tailored to their specific measurement applications. We will discuss the technical details of the PurSamurAI signal processing architecture and evaluate its real-time performance capabilities.

Sci-Compiler: Towards Cross-Platform FPGA Development and Automated CI/CD Workflows for Scientific Data Acquisition (#3405)

Andrea Abba[1], Stefano Carsi[1], Davide Bianchi[1], Francesco Caponio[1], Alberto Cusimano[1], Valentina Arosio[1], Monica Lazari[1], Alessando Giannini[1], Simone Cuzzolin[1], Yuri Venturini[2], Gianluca Beccuzi[2], Matteo Bianchini[2], Luca Colombini[2], Carlo Tintori[2], Annalisa Mati[2]

[1] Nuclear Instruments SRL, Lambrugo, Italy; [2] CAEN S.P.A., Viareggio, Italy

Abstract

Sci-Compiler is a graphical FPGA development environment for custom digital signal processing and data acquisition in nuclear physics, radiation detection, and scientific instrumentation. This contribution presents a major evolution of the platform, including the highly anticipated introduction of Linux support and automated firmware compilation through CI/CD pipelines.

The new alpha release for Linux represents a significant milestone, addressing a long-standing requirement from the scientific community and enabling Sci-Compiler to operate natively in Linux-based research environments. Together with newly introduced pipeline licenses, it opens the way to automated FPGA compilation, integration with Git-based workflows, reproducible firmware builds, and continuous validation of scientific instrumentation firmware.

The signal processing library has been substantially expanded with advanced FFT/IFFT architectures, real-time frequency-domain filtering, programmable FIR and CIC filters, digital modulation, waveform averaging, statistical analysis, and configurable signal generators. Extensive support for time-multiplexed processing enables efficient implementation of multichannel algorithms for high-sampling-rate digitizers.

Detector-oriented developments include improved trapezoidal processing for high-count-rate spectroscopy, pile-up rejection, rise-time discrimination, and flexible event packet generation. Extended simulation capabilities allow acquisition chains to be tested and waveforms, spectra, and event streams to be exported without physical hardware.

A redesigned graphical editor further improves productivity through intelligent signal connections, searchable processing blocks, hierarchical design tools, and integrated documentation.

These advances mark a transition towards an accessible, cross-platform and automated FPGA development ecosystem for modern scientific experiments.

TS-02-06

Broadcom's Silicon Photomultiplier: Technology, Performance, Status and Roadmap (#3399)

Stefan Brunner, on behalf of the Broadcom SiPM team

Broadcom Inc, Regensburg, Germany

Abstract
This presentation provides an overview of Broadcom's silicon photomultiplier (SiPM) and photodetection technologies, including NIR- and NUV-SiPMs. Special focus is placed on initial results for the new HDR-NUV-MT SiPM, as well as the newly developed BroadR and NUV-DJ SiPM technologies.
HDR-NUV-MT We present the recently released HDR-NUV-MT SiPM, a 3×3 mm² device designed for applications requiring high dynamic range. This is achieved using an 18 µm SPAD pitch, combined with a fast recharge time constant of about 17 ns. Additionally, this is the first SiPM in the NUV family featuring four subsegmented quadrants that can be read out individually.
BroadR The newly developed BroadR technology utilizes a novel SPAD architecture enabling an unprecedented flat spectral response. A high photon detection efficiency (PDE) of 50% is maintained from 400 nm to 750 nm, bridging the spectral ranges traditionally covered by separate NUV- and NIR-SiPM technologies. Along with the high and flat PDE, the BroadR technology offers superior dynamic range. Indeed, the this PDE level is achieved with a SPAD pitch of 14 µm and a recharge time constant that can be designed to be well below 10ns.
NUV-DJ The NUV-DJ technology significantly increases PDE at wavelengths above 420 nm compared to NUV-MT, while maintaining excellent NUV sensitivity from 250 nm to 420 nm. At 500 nm, PDE improves from 52% to 62% with the same 40 µm SPAD pitch. The correlated noise of NUV-DJ is also lower compared to NUV-MT at the same PDE. This high PDE and low noise enable best-in-class coincidence time resolution (CTR) for LYSO-based TOF-PET, expand applications to green-emitting scintillators like GAGG, and enable BGO-based Cherenkov TOF-PET. Initial characterization results for NUV-DJ will be presented.

Broadcom's NUV SiPMs find application in TOF-PET, Cherenkov-PET, radiation spectroscopy, photon-counting X-ray detection & PCCT, flow cytometry, and time-gated fluorescence.

SimSET | SimSET User Meeting (onsite only)

Chairs:
Paul E. Kinahan (Seattle)
Robert S. Miyaoka (Seattle)

Summary

The Simulation System for Emission Tomography (SimSET) toolkit has been in the nuclear medicine physics research landscape for over 30 years. First released in 1993, SimSET has become a primary resource for many nuclear medicine imaging research groups around the world.

The University of Washington Imaging Research Laboratory and collaborators are continuing to develop SimSET, adding new functionality and utilities. The direction of development is driven in part by the SimSET users.

We encourage SimSET users, or those just interested, to participate in the meeting to learn about proposed developments, provide feedback and new directions, and to meet other users.

Recent Advances in Photosensors and Radiation Detectors for Nuclear Science and High Energy Physics (#3391)

Mauro Bombonati

Hamamatsu Photonics Italia Srl, Arese, Italy

The work presented here reflects the contributions of numerous colleagues across Hamamatsu Photonics. The author gratefully acknowledges the efforts of the photosensor, detector, device development and application engineering teams in Japan, whose expertise and continuous innovation make these developments possible.

Abstract
Hamamatsu Photonics continues to develop a broad portfolio of photosensors and radiation detector technologies addressing the evolving requirements of nuclear science, high energy physics, medical imaging, and related applications. This presentation will provide an overview of recent developments across several detector platforms, including silicon photomultipliers (SiPMs), advanced silicon electron multiplication devices, vacuum photodetectors, and emerging radiation detection technologies. Particular attention will be given to ongoing efforts aimed at improving photon detection efficiency, noise performance, timing characteristics, operation in demanding environments and detector integration. The presentation is intended as an overview of current development activities, providing attendees with insights into emerging detector solutions and their potential impact on future nuclear science and high energy physics experiments.

Introduction to Representative Achievements of Jinan Laboratory of Applied Nuclear Sciences in the Field of Nuclear Technology Applications (#3425)

Kunliang Liu[1,2], Xiaolei Yang[1,3], Guangbin Wei[1,3], Jie Cao[1,3], Xianhui Xie[1,3], Ray Image Testing Technology；The Palace Museum；Shandong Nuclear Power Co., Ltd

[1] Jinan Laboratory of Applied Nuclear Sciences, Department of Research management, Jinan, China; [2] Institute of High Energy Physics, Chinese Academy of Sciences, Nuclear Technology Application Center, Beijing, China; [3] CAEA Center of Excellence on Nuclear Technology Applications for Nuclear Detection and Imaging, Jinan Base, Beijing, China

This work is supported by Jinan Haiyou Talents Introduction Program.

Abstract

Jinan Laboratory of Applied Nuclear Sciences is a research platform established by the Institute of High Energy Physics, Chinese Academy of Sciences. Our team focuses on nuclear technology applications in three key areas: non-destructive testing, radiation monitoring, and molecular imaging. We have developed and industrialized a broad portfolio of nuclear instruments. This presentation introduces our recent achievements and flagship products.

Non-destructive testing — We invented the world's first curved-surface XRF spectrometer used for cultural heritage conservation, producing high-resolution 3D elemental maps of irregular bronze and jade relics. It has analyzed precious artifacts for the Palace Museum and other museums.

Radiation monitoring — Our portfolio includes personal dosimeters, portable gamma cameras, radionuclide identifiers, neutron detectors, and nuclear electronics modules. Over 3,000 units are in service at universities, nuclear power plants, and hospitals. Our digital monitoring system supports wide-area imaging and semi-quantitative analysis to safeguard plant operations.

Molecular imaging — Our panoramic small-animal PET-CT offers a 213 mm axial FOV, capturing whole-body dynamic rat imaging in a single bed position at sub-millimeter resolution for radiopharmaceutical R&D. XTOMO-CUBE, the world's smallest micro-CT, is compact, portable, and domestically built, delivering micron-resolution 3D reconstruction for archaeology, materials research, and teaching.

Core components — We have also independently developed 150 kV X-ray source components with decetn in-lab performance, and we are carrying out equipment integration to further validate and optimize this technology.

Visit us at Booth 53 for specifications, application cases, and live demos. We look forward to discussing collaboration with you.

WIE & YP | WIE & YP

Chairs:
Audrey Corbeil Therrien (Sherbrooke)
Andrea Gonzalez Montoro (Valencia)

Join us at the IEEE 2026 WIE+YP Event in Granada for an interactive and engaging experience focused on career development, leadership, networking, and collaboration within the NPSS community.

We have prepared a dynamic program with inspiring discussions, interactive activities, and opportunities to connect with colleagues and friends from different career stages and technical backgrounds. Whether you are a student, postdoc, young professional, or senior researcher, we hope this event will provide a welcoming space to exchange experiences, build new connections, and strengthen our community.

The event will include a complimentary lunch, a few YP goodies, great networking opportunities with friends and colleagues, and a lineup of very engaging activities.

We are really looking forward to seeing you in Granada!

STIR | STIR Users' & Developers' Meeting (onsite only)

Summary

STIR is Open Source software for use in tomographic imaging. Its aim is to provide a Multi-Platform Object-Oriented framework for all data manipulations in tomographic imaging. The emphasis is on image reconstruction in emission tomography (PET and SPECT). During the annual meeting experienced users and developers will present their recent work with STIR with technical emphasis on software and algorithmic development and demos. Additional time will be allowed for discussion between the speakers and the audience. If interested in presenting contact the chairs before the 1st of September.

For up-to-date information please always check STIR website: https://nssmic.ieee.org/2026/hannah-wakeling/

Author Index

This project has received financial support from the CNRS through the MITI interdisciplinary programs. MIC-21-05 1463
This work is supported by the EPSRC-funded UCL Centre for Doctoral Training in Intelligent, Integrated Imaging in Healthcare (i4health) (EP/S021930/1), the National Physical Laboratory (NPL) and the UK National Measurement System of the UK Government's Department for Science, Innovation and Technology (DSIT). SIRF and STIR software maintenance is part-funded via CCP SyneRBI (funded by the EPSRC grant EP/T026693/1) and by STFC through the UKRI Digital Research Infrastructure programme. 1379
This work was supported in part by the Consortium for Monitoring, Technology, and Verification under Department of Energy National Nuclear Security Administration, award number DE-NA0003920. NSS-05-01 477
